THE COMMON HEPATIC DUCT

Two main ducts (right and left hepatic) issue from the liver and unite near the right end of the porta hepatis to form the common hepatic duct, which passes downwards for about 3 cm, and is joined on its right side and at an acute angle by the cystic duct; by the union of the common hepatic with the cystic duct, the bile duct is formed (**8**.141). The common hepatic duct is on the right of the hepatic artery proper and in front of the portal vein.

THE GALL BLADDER

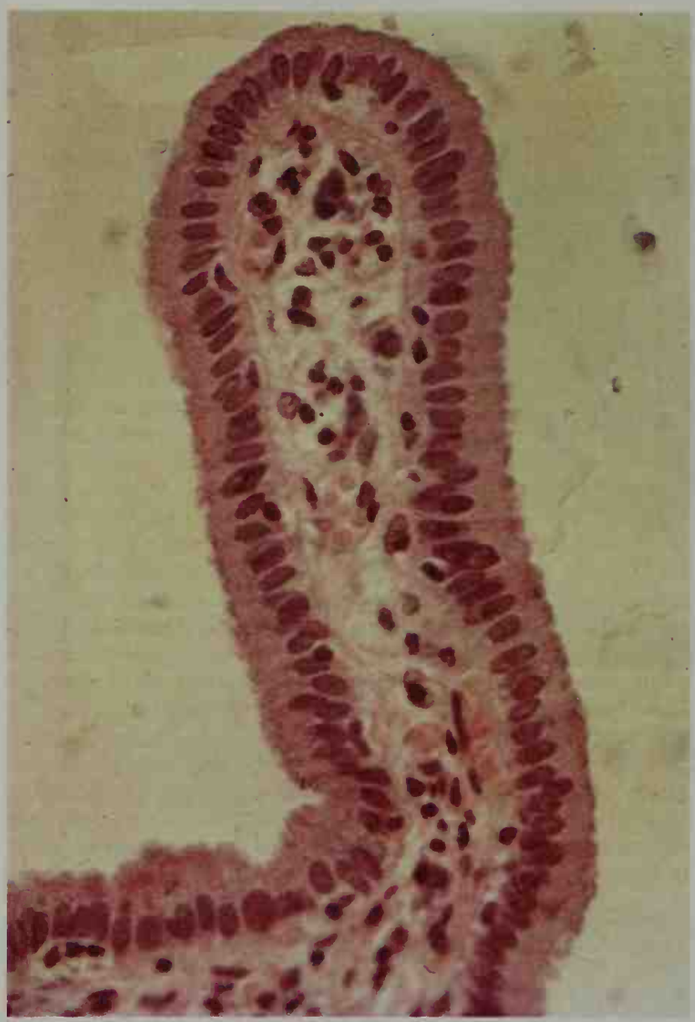
The gall bladder (**8**.135, 141, 142) is a slate-blue, piriform sac partly contained in a fossa on the inferior surface of the right hepatic lobe, extending from near the right extremity of the porta hepatis to the inferior border of the liver. Its upper surface is attached to the liver by connective tissue; its under surface and sides are covered with peritoneum continued from the surface of the liver. Occasionally it is completely invested with peritoneum and may be connected to the liver by a short mesentery. It is from 7 to 10 cm long, 3 cm broad at its widest part, and from 30 to 50 ml in capacity. It is divided into a fundus, body and neck.

The *fundus* or expanded end, is directed downwards, forwards and to the right. It projects beyond the inferior border of the liver, and comes into relationship with the posterior surface of the anterior abdominal wall below the ninth right costal cartilage, behind the point where the lateral edge of the right rectus abdominis crosses the costal margin; posteriorly the fundus is in relation with the transverse colon, near its commencement. (These relations are, however, considerably altered when the gall bladder descends lower in the abdomen, as it frequently does, particularly in slender females. *See* Fleischner and Sayegh 1958.) It is entirely covered with peritoneum. The *body* is directed upwards, backwards and to the left; near the right end of the porta hepatis it is continuous with the neck. It is in relation by its upper surface with the liver; by its under surface with the right part of the transverse colon; and further back with the superior part of the duodenum and the upper end of the descending part. The *neck* is narrow; it curves upwards and forwards, and then, turning abruptly backwards and downwards, becomes continuous with the cystic duct; at its point of continuity with the cystic duct there is a constriction. The neck is attached to the liver by areolar tissue in which the cystic artery is embedded. The mucous membrane which lines the neck projects into its lumen in the form of oblique ridges, forming a sort of spiral valve; when the neck is distended, this valve causes the surface of the neck to present a spiral constriction.

8.142 Dissection to show the relations of the hepatic artery, bile duct and portal vein to each other in the lesser omentum. Anterior aspect.

From the right wall of the neck of the gall bladder a small pouch may project downwards and backwards towards the duodenum. This pouch, often termed Hartmann's pouch (although originally described by Broca) has been widely regarded as a constant feature of the normal gall bladder, but investigations (Davies and Harding 1942) have shown that it is always associated with pathological conditions, especially dilatation. When the pouch is well marked, the cystic duct arises from its upper and left wall and not from what appears to be the apex of the gall bladder.

The cystic duct (**8**.141, 142), from 3 to 4 cm long, passes backwards, downwards and to the left from the neck of the gall bladder, and joins the common hepatic duct to form the bile duct; it runs parallel with and adheres to the common hepatic duct for a short distance before joining with it. The junction is usually situated immediately below the porta hepatis, but it may be at a considerably lower level. In the latter event the cystic duct lies in the right free margin of the lesser omentum. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall bladder. They project into the duct in regular succession, and are directed obliquely round the tube, presenting much the appearance of a crescentic, *spiral valve* (**8**.141). When the duct is distended, the spaces between the folds are dilated, and the exterior of the duct appears twisted in the same manner as the neck of the gall bladder.



The bile duct is formed near the porta hepatis by the junction of the cystic and common hepatic ducts; it is usually about 7·5 cm long and about 6 mm in diameter (*vide infra*).

It runs at first downwards, backwards and slightly to the left, anterior to the epiploic foramen; here it lies in the right border of the lesser omentum, in front of the right edge of the portal vein, and on the right of the hepatic artery proper (**8**.142). It passes behind the superior part of the duodenum with the gastro-duodenal artery on its left, and then runs in a groove on the upper and lateral part of the posterior surface of the head of the pancreas (**8**.131); here it is situated in front of the inferior vena cava, and is sometimes completely embedded in the pancreatic tissue (pp. 1370, 1373). It has been pointed out (Lytle 1959) that the bile duct may lie close to the left border of the descending part of the duodenum or lie as far away as 2 cm from the duodenal wall, and that, even when the duct is embedded in the pancreas, its position is indicated by a groove on the back of the head of the pancreas. This groove can be palpated by the fingers of the left hand passed behind the descending part of the duodenum, with the thumb on the front of the head of the pancreas to act as a counter pressure, and through the groove stones in the bile duct may be detected and removed. At the left side of the descending part of the duodenum the bile duct comes into contact with the pancreatic duct and accompanies it into the wall of this part of the gut, and there the two ducts usually unite to form the *hepatopancreatic ampulla* (p. 1370); the distal, constricted end of this ampulla opens into the descending part of the duodenum on the summit of the major duodenal papilla (**8**.132) situated about 8 to 10 cm from the pylorus (p. 1344).

The bile duct may be indicated on the anterior surface of the abdomen by a line which begins 5 cm above the transpyloric plane and 2 cm to the right of the median plane, and runs downwards for 7·5 cm.

Vessels and Nerves

The *cystic artery* and its distribution are described in some detail on p. 714 and the *cystic veins* on p. 765. The lower part of the bile duct receives several branches from the *posterior superior pancreatico-duodenal artery* (p. 714), while the upper part of the bile duct and the hepatic ducts are supplied with branches from the *cystic artery*. The *right hepatic artery* gives branches to the middle part of the bile duct, though these are very small, the main supply being from the *cystic* and *posterior superior pancreaticoduodenal arteries*. There is considerable variation in the arrangement of the above vessels (Shapiro and Robillard 1948; Michels 1962). The posterior superior pancreaticoduodenal artery ends below by anastomosing with the posterior branch of the inferior pancreaticoduodenal artery in the vicinity of the hepatopancreatic ampulla; in cases where this anastomosis is poor, ligation of the posterior superior pancreaticoduodenal artery may result in gangrene or stricture of the bile duct (Henley 1955). The *veins* from the upper part of the bile duct and the hepatic ducts, like those from the gall bladder and cystic duct, generally enter the liver directly, while those from the lower part of the bile duct enter the portal vein. The *lymph vessels* of the gall bladder and bile ducts are described on p. 794. The *nerves* of the gall bladder, which are sympathetic and parasympathetic, are derived from the

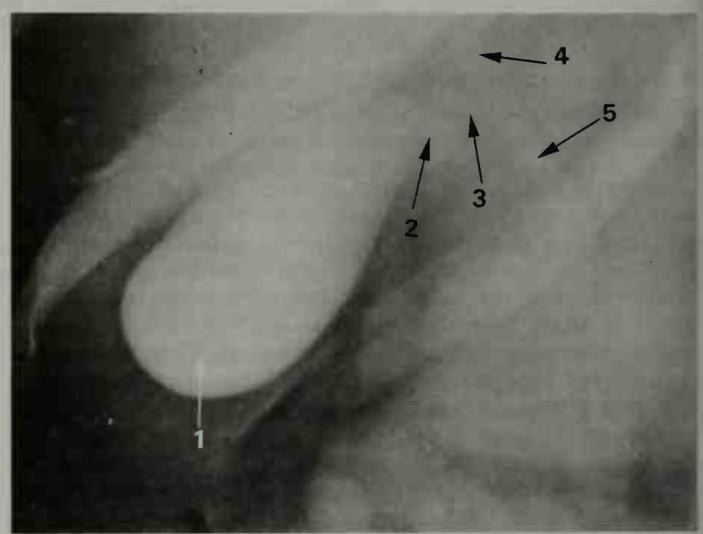
8.143 A section through a surface projection (ruga) of the gall bladder showing the columnar epithelial cells and lamina propria. Haematoxylin and eosin. Magnification × 500.

coeliac plexus and pass along the hepatic artery and its branches. Autonomic plexuses are present in the muscular and submucous layers, and the occurrence of ganglion cells, presumably parasympathetic, in these plexuses has been confirmed in monkeys (Sutherland 1966, 1967). Fibres from the right phrenic nerve, through the communications between the phrenic plexus and the coeliac plexus, also appear to reach the gall bladder in the hepatic plexus, as evidenced by the referred 'shoulder pain' experienced in diseases of the gall bladder.

VARIATIONS IN GALL BLADDER AND BILE DUCTS

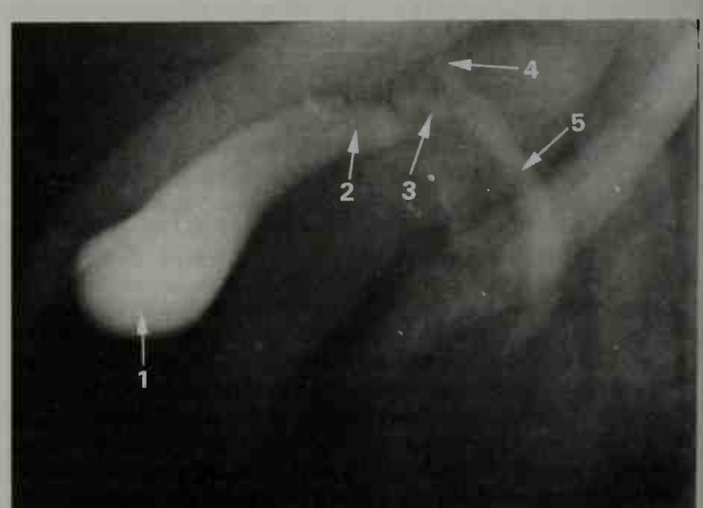
The gall bladder frequently varies in size and shape; in rare cases it may be (*a*) duplicated (Mincsev 1967), the two gall bladders having separate ducts or a common cystic duct, or (*b*) absent, though the cystic duct may be present in a few of these cases.

The level of junction of the cystic and common hepatic ducts varies from the porta hepatis to behind, or even below, the superior part of the duodenum; when the junction is low the two ducts in their course may be closely connected by fibrous tissue, rendering it very difficult, in removing the gall bladder, to clamp the cystic duct without injuring the common hepatic (or the main bile) duct. Occasionally the cystic duct joins the right hepatic duct. The cystic duct may pass to the left behind, or in front of, the common hepatic duct and then joins the latter on its left surface. Accessory hepatic ducts may emerge from the liver, more frequently from its right lobe, to join the main hepatic ducts, or very rarely the gall bladder itself. Rarely, a failure of canalization of the bile ducts during prenatal development leads to congenital atresia or stenosis of these ducts with fatal results in a few months after birth. The bile duct and pancreatic duct may open separately into the duodenum or they may join together before passing through the duodenal wall. Variations of the arteries related to the bile ducts are much more common than those of the bile ducts themselves. (For the variations in the hepatic arteries, *see* p. 713.) For further information consult Santulli and Blanc (1961); Boyden *et al.* (1967).



STRUCTURE OF GALL BLADDER AND BILIARY DUCTS

The wall of the gall bladder displays three layers: serous, fibromuscular and mucous.



The *serous layer* is derived from the peritoneum; it completely invests the fundus, but covers only the inferior surfaces and sides of the body and neck. Beneath it lies a subserous layer of areolar tissue.

The *fibromuscular layer* is a stratum of fibrous tissue, mixed with nonstriated myocytes ('fibres'); these are arranged in loose bundles disposed in longitudinal, circular and oblique directions.

The *mucous layer* is loosely connected with the fibrous layer. It is generally of a yellowish-brown colour, and is elevated into minute rugae giving it a honeycomb appearance (**8**.141, 143). The epithelium consists of a single layer of columnar cells which vary in size with species. Electron microscope investigation (Chapman *et al.* 1966) of the gall bladder epithelium of the dog shows the presence of microvilli on the apical surface; these structures are

8.144A An anteroposterior radiograph of the gall bladder and biliary ducts after the oral adminstration of sodium tetra-iodophenolphthalein the previous day.

8.144B The same field as **8**.144A but taken twenty minutes after a fatty meal, demonstrating the contraction and partial emptying of the gall bladder. In both A and B; (1) fundus of gall bladder; (2) neck of gall bladder; (3) cystic duct; (4) common hepatic duct; and (5) the bile duct.

regularly arranged and between their bases pinocytotic activity is observed. The basal intercellular spaces show considerable dilatation and many capillaries lie close to the basement membrane. These features indicate active absorption of water and solutes from the bile, rendering it more concentrated. The basal intercellular spaces are particularly large when active water absorption is occurring (Kaye *et al.* 1966). The mechanism of bile concentration appears to involve the active transport of sodium and calcium which creates an osmotic gradient from the lumen of the gall bladder, to the capillaries of the lamina propria. Mucous granules are present in the apical half of some cells, particularly those near the duct; these are secreted into the lumen (Johnson *et al.* 1962; Mueller *et al.* 1972).

The coats of the large biliary ducts are an external or fibrous, and an internal or mucous. The fibrous layer is composed of fibroareolar tissue, intermingled with a few nonstriated muscle fibres that are arranged in a longitudinal, oblique and circular manner. (In one investigation, muscle fibres were detected in only 12 out of 100 human common bile ducts—*see* Mahour *et al.* 1967.) The mucous layer is continuous with the lining membrane of the hepatic ducts and gall bladder, and also with that of the duodenum; like the mucous membrane of these structures, its epithelium is of the columnar variety; many lobulated mucous glands are present. In the bile duct the mucous membrane is provided with numerous tubulo-alveolar glands that are not evenly distributed throughout the mucosa but are arranged in clusters. The glands secrete mucin, at least some of which is of the sulphated variety (McMinn and Kugler 1961). An electron microscope study of the bile duct epithelium of the guinea-pig shows that microvilli are present on the luminal surface of the cells. Secretion granules, some composed of mucus, are found in the apical cytoplasm. The epithelial cells in the rat, which has no gall bladder, can be divided into two types, termed light and dark, owing to a difference in electron density. The light cell has longer and more regular microvilli, but the basal intercellular space between adjacent dark cells is greater. The mucous membrane appears to actively modify the bile and thus, in this species, compensates for the absence of a gall bladder (Riches and Palfrey 1966).

The circular muscle around the lower part of the bile duct, including the ampulla and the terminal part of the main pancreatic duct, is thickened and is called the *sphincter of the hepatopancreatic ampulla* (or the *sphincter of Oddi*). The latter comprises musculature at three levels: (*a*) at the end of the bile duct (*sphincter ductus choledoci*); (*b*) around the terminal part of the pancreatic duct (*sphincter ductus pancreatici*); and (*c*) around the ampulla. Only the choledochal sphincter is constantly present. The mechanism for the emptying of the gall bladder appears to be under hormonal, rather than nervous, control. The presence of fat or acid in the duodenum is believed to cause the liberation of a hormone (cholecystokinin) which stimulates the gall bladder to contract. When the pressure of the stored bile in the gall bladder exceeds 100 mm of bile, the gall bladder contracts, the sphincter of Oddi relaxes and bile is poured into the duodenum. It has been maintained (Kirk 1944) that there is no sphincteric arrangement of the musculature around the opening of the bile and pancreatic ducts into the duodenum, but that the sphincter of Oddi surrounds the bile duct as it passes through the submucosal zone of the duodenal wall and is continuous with the circular muscle coat of the duodenum, which is thickened at this site. However, subsequent studies suggest strongly that in man and other primates there is a common sphincteric apparatus surrounding both ducts, and that the common bile duct has a second sphincter of the type described above (Boyden 1957, 1966). The terminal part of the united bile and pancreatic ducts is packed with villous, valvular folds of the mucous membrane, and the muscle fibres extend into the connective tissue cores of these folds. This arrangement suggests that contraction of the muscle fibres results in retraction and erection or aggregation of the folds, thus preventing reflux of duodenal contents into the ducts and controlling the exit of bile into the duodenum. In the cat, stimulation of branches of the vagus nerves to this region results in relaxation of the opening of the bile duct into the duodenum; in the human, the *myenteric (Auerbach's) plexus* is well developed at the site of termination of the ducts. Inflammatory swelling of the villous folds may obstruct the ducts.

Applied Anatomy. On account of its large size, its fixed position, and its friability, the liver may be accidentally ruptured and haemorrhage may be severe, because the hepatic veins are contained in rigid canals in the liver and are unable to contract. The liver may be torn by the end of a broken rib perforating the diaphragm.

There is clinical evidence that the bloodstreams conveyed to the portal vein by the superior mesenteric vein and the splenic vein remain largely separate from each other in the portal vein, and pass respectively along the right and left branches of the portal vein to the right and left physiological lobes (p. 1374) of the liver, e.g. malignant or infective emboli may be more pronounced in the right lobe than the left, if the primary infection lies in a part of the gut drained by the superior mesenteric vein, and in the left lobe if the primary site is in splenic vein or inferior mesenteric vein territory. Some injection experiments in living animals also indicate the tendency for the two venous streams to remain separate in the portal vein.

The results of studies on the vascular segments of the liver were referred to previously (p. 1376); such information is essential to the successful performance of the modern surgical operation of *partial hepatectomy*. As yet, attempts at *liver transplantation* are still tentative.

The gall bladder may become distended by obstruction of the cystic duct or by gall stones within it, and may form a large swelling which projects downwards and forwards towards the umbilicus. It moves with respiration, since it is attached to the liver.

Obstruction of the bile duct, apart from stone, is often due to occlusion of this canal by pressure of malignant tumours, especially those commencing in the pylorus or pancreas. It is also seen following ulceration of the duct, cicatricial contraction of the scar tissue taking place. Enormous distension, both of the bile duct itself and of its radicles in the liver substance, may occur.

Cholecystography (**8**.144). The gall bladder is not opaque to X-rays. If certain radio-opaque substances are given orally or intravenously, they are excreted by the liver from the blood into the bile. In the gall bladder the substance is concentrated and thus becomes more opaque to X-rays. In this way the form, position and emptying process of the gall bladder can be demonstrated radiographically. By this means it has been shown that the position and form of the gall bladder vary with the general body build (somatotype) of the individual (Davies 1927). In broad (hypersthenic) types the gall bladder is broad and lies high up and far laterally (at the level of the first lumbar vertebra), whereas in narrow (asthenic) types it is narrow, lies more medially and may reach as low as the fourth lumbar vertebra.

THE UROGENITAL SYSTEM

Introduction

So customary has it become to link the organs concerned with urinary excretion and reproduction as the *urogenital system*, that the suitability of this amalgamation is rarely even questioned. Yet functionally the two have nothing in common, and to associate them in description may seem at first absurd (Romer 1970). In fully developed human organs there is little more structural overlap than the use of the male urethra both as a urinary and seminal duct. Of course, in their embryological development, the gonadal ducts have a *nephric* origin; but in the human female even the *oviduct* ('female', paramesonephric or Müllerian duct) is no

longer formed from nephric tissue, and there is, indeed, no adequate reason to continue to define a 'urogenital' system in female mammals in general. Even in the human male, as in other mammals, in which the duct system of the testis is derived from nephric tubules and the *mesonephric duct*, these no longer function as excretory structures. In reptiles the functional kidney is no longer a mesonephros; and the intromittent *penis*, developed from cloacal tissues, consists of two bilateral parts, which enclose a purely seminal groove when erected for copulation, urine being voided into the cloaca. Apart from its development, therefore, the genital system has already achieved complete dissociation from the urinary organs in both sexes at the level of reptilian evolution. Birds, like amphibians, have no intromittent organ, though this is probably a secondary loss in the avian group, some more primitive birds possessing a rudimentary penis of reptilian type.

In all vertebrates (as distinct from elementary chordates) the nephric excretory tubules and the gonads develop from the coelomic epithelium, together with their collecting ducts as they evolve. Both develop in a dorsal situation on each side of the major vessels of the body; and it is perhaps this propinquity, combined with the more medial location of the gonads, which has led to the adoption of urinary ducts and tubules to serve the gonads, especially in the male.

In elementary *Chordata*, such as *Amphioxus*, the excretory tubules, or *nephridia*, have *glomeruli* or capillary 'tufts' close to them, and they secrete from the adjoining bloodstream and the coelom directly into a peribranchial space, the atrium. These excretory organs are ectodermal in origin and are unrelated to the mesodermal nephric tubules of vertebrates. The evolutionary relationship of *Amphioxus* to the early vertebrates is, in any case, uncertain; it has even been suggested that this chordate is itself a paedomorphic form of a primitive vertebrate (Grassé 1948; Young 1962) but these are matters which cannot be discussed here.

In vertebrates living in water, whether saline or fresh, the problems of preserving internal osmotic constants in blood and body fluids, despite variable and sometimes very large intakes of water and salts, has led to a continuous evolution of more efficient and usually more elaborate excretory tubules. These are derived from mesoderm intermediate between the somites and the lateral plate in the embryo, forming structures named *nephrotomes* (p. 210). Though these arise segmentally, their large numbers overshadow this, and in most lower vertebrates they form elongated masses or cords of nephrogenic tissue projecting into the coelom in a dorsolateral position. The gonads develop medial to these *nephrogenic cords* (p. 210); and since the *primary excretory ducts* (p. 210), carrying urine to the exterior, evolve lateral to the nephros, gonadal access to them is effected by adaptation of nephric tubules. The degree of development and functional status of different parts of the elongate vertebrate kidney, or *holonephros*, extending through many body segments, has displayed much variation in different forms. There is a tendency for the most cranial part of the kidney to disappear, except where it functions during embryonic life or in a larval form, as in some cyclostomes (e.g. *Petromyzon*, the lamprey). In the anamniotic gnathostomes (fish and amphibia) an intermediate nephrogenic region develops into a functional kidney, and while this is still elongate in shape, it occupies a comparatively small number of body segments, with which its vascular connexions approximately accord. In the reptiles and mammals an even more caudal mass of nephrotomes differentiates into the definitive kidney, which becomes a more localized and rounded organ, of familiar reniform shape, particularly in mammals, losing almost all indications of a plurisegmental origin in its full development.

This progressive caudal shift of the functioning kidney has prompted a division of the nephrogenic mass into pro-, meso-, and meta-nephros, giving rise to somewhat misleading concepts. The amphibian kidney, for example, is often described as a mesonephros, and the mammalian organ as a metanephros; nevertheless, the mode of formation of the nephric tubules is substantially the same at all levels, and it cannot be assumed that these regional terms can be applied over large and diverse vertebrate groups with anything more than approximate segmental uniformity. The terms are perhaps more of a descriptive convenience than vehicles of biological truth. (For a discussion of these and other problems in the development of the urogenital organs, consult Fraser 1950.)

Distinctions between the three regional levels of the nephrogenic ridge depend more upon their functional status and duct systems than their intrinsic morphology. Primitively, in cyclostomes, the excretory tubules discharge their products, as do the gonads their gametes, into the coelomic cavity, from which they escape to the exterior through the *abdominal pores* or short ducts situated in a caudal position. In gnathostomes, the *nephric tubules* lose continuity with the coelom, developing a saccular extremity, with each of which a *glomerulus* becomes closely related. The tubules establish continuity with a longitudinal *archinephric duct* (*primary excretory duct*), which at first serves the pronephros, and is taken over by the succeeding more caudal part of the kidney, the mesonephros. It is through mesonephric tubules that the testis establishes an outlet through the urinary duct, the arrangement typical of amphibians. Both urine and spermatozoa reach the cloaca through such *mesonephric* (Wolffian) *ducts*. The ovary also acquires a duct, which in some forms is derived from the mesonephric duct; but this *paramesonephric*, *female*, or *Müllerian duct*, becomes a separate entity and does not function as a channel for transmission of urine. Moreover, the oviduct never establishes direct continuity with the ovary, which retains its primitive habit of shedding ova into the coelom, though in very close proximity to the open, coelomic beginnings of the oviduct. (This relationship is constant and occurs in the human female. The oviduct of mammals, and of tetrapods in general, appears to develop independently by evagination from the coelomic lining.)

In reptiles, birds and mammals, the functioning kidney is a *metanephros*, developing caudal to the mesonephros. Its main distinction is that it has no association with genital function, developing in part as an outgrowth of the caudal region of the mesonephric duct, but ultimately forming a separate opening into the bladder by its own duct, the *ureter*. The mesonephros is thus relieved of all excretory function, its tubules and ducts persisting only in so far as they are modified to form the *vasa efferentia* of the testis, the *epididymis* and *ductus deferens*.

To summarize—the pronephros is an embryonic or larval excretory organ, having a duct which is purely excretory. The mesonephros, which takes over this duct and the function of excretion, also provides a pathway for the conduction of spermatozoa to the exterior, and also, in some vertebrates by division of its duct, a separate exit for ova. The metanephros is again a purely excretory organ, the male genital ducts continuing as mesonephric derivatives, and the oviduct as an increasingly independent development.

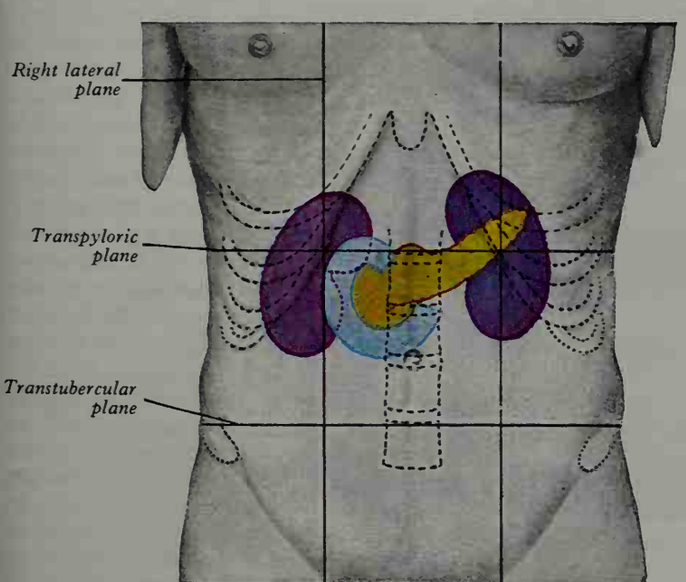
The complete segregation of urinary and genital organs in the reptiles—apart from their embryonic development and the opening of their separate ducts in a common cavity, the cloaca—becomes modified once more by the evolution of a male intromittent organ to effect the internal fertilization associated with full emancipation from reproduction in water. The production of eggs, or rather embryos, protected from desiccation in a terrestrial environment by shells impervious to water (though not to respiratory gases), necessitates the fusion of gametes in the oviduct proximal to specialization of its wall to produce such coverings. Similarly, the production of offspring which have already reached a sufficient stage of development to live exposed to the external environment naturally also entails internal fertilization. Apart from monotremes, all mammals exhibit this viviparous habit. Although internal fertilization is accomplished without an intromittent organ in birds, an intromittent and hence erectile *penis* is universal in marsupials and eutherian mammals. Since this is traversed by the urethra, used to void both urine and semen, the male mammal, including mankind, exhibits to this extent an association of excretory and reproductive organs. Both systems display many adaptations and specializations, which in mammals are concerned with greatly improved ability to preserve a steady internal environment in terms of total body water volume, and the concentrations of ions and other dissolved substances. This entails an increasing complexity in the structure of glomeruli and renal tubules, forming the *nephrons* or kidney

units, capable not only of removing variable and sometimes large volumes of water from the body, but also of selective reabsorption of some substances such as glucose and salts, and the retention of others, such as urea, in the urine.

The kidney ducts open into various forms of reservoir in many vertebrates, and in mammals a cloacal derivative the *bladder*. In the reproductive organs of mammals a number of accessory structures have evolved in connexion with intromission in the male, and the retention and nurture of developing embryos in the female. These include the seminal vesicles and prostate, the uterus and vagina. All these developments have already been considered in their embryological development in a previous section (p. 210); they must now be studied in their fully developed primate morphology. The customary association of the two groups of organs has been retained, since even in description of the completely differentiated urinary and genital systems reference to their ontogeny and phylogeny will occasionally be necessary. It is, nevertheless, perhaps worthy of repetition that their association in the post-natal human being is limited to the dual function of the penile urethra.

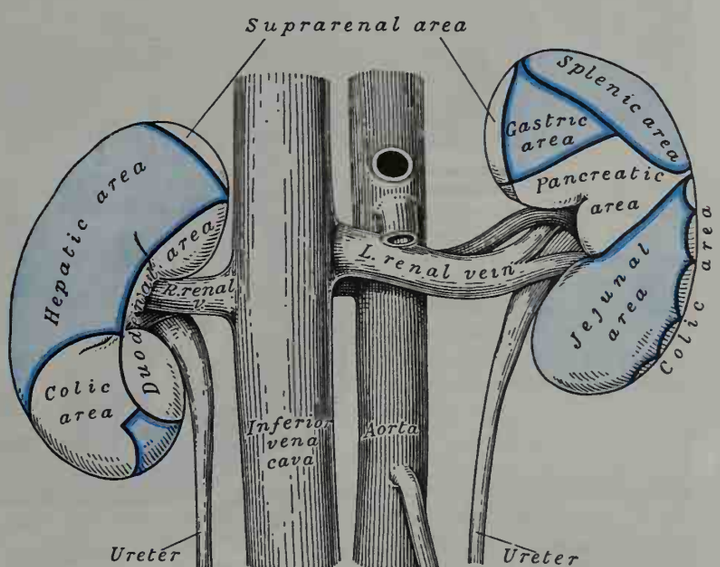
THE URINARY ORGANS

The urinary organs comprise: (1) the *kidneys* (renes), which 'secrete' the urine; (2) the *ureters*, which convey it to (3) the *urinary bladder* (vesica urinaria), where it is stored temporarily; and (4) the *urethra*, through which it is discharged from the urinary bladder. It must be added that while the female urethra is purely a urinary duct, the male urethra serves two functions—urinary and reproductive. Of these the latter is essential, and the former function merely utilizes a tube which is almost entirely genital. Loss of the penile urethra need not greatly affect urination, whereas the genital function is for all practical purposes abolished. It would, therefore, be more logical to include almost the whole of the urethra with the rest of the genitalia in the male.



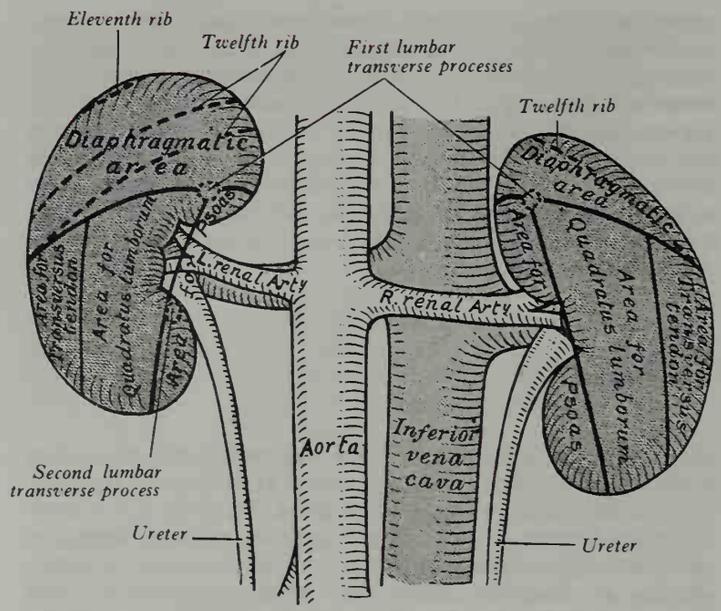
The Kidneys

The kidneys excrete end products of the metabolic activities of the body and excess water, and are thus essential in controlling the concentration of the constituents of the body fluids, maintaining, for example, the electrolyte and water balance in the tissue fluids. They also have an endocrine function, producing and releasing into the bloodstream *erythropoietin*, which affects blood formation, *rénin* which influences blood pressure, and *1,25-hydroxycholecalciferol*, which is involved in the control of calcium metabolism. The last of these hormones is a derivative of vitamin D and may modify the action of parathyroid hormone (O'Riordan 1978). The kidneys are two reddish-brown organs situated in the posterior part of the abdomen, one on each side of the vertebral column, behind the peritoneum; they are surrounded by a mass of adipose connective tissue. Their cranial ends are level with the superior border of the twelfth thoracic vertebra, their caudal limits with the third lumbar vertebra. The right kidney is usually slightly inferior to the left, probably on account of its relationship to the liver; the left is a little longer and narrower than the right and is a little nearer to the median plane. The long axis of each kidney is directed downwards and laterally, the transverse axis posterolaterally. This entails that the anterior and posterior aspects, as described below, are in fact *anterolateral* and *posteromedial*; but the simpler terms have been retained for brevity. The transpyloric plane (p. 1320) passes through the superior part of the hilum of the right kidney, and through the inferior part of the hilum of the left.



Each kidney is about 11 cm in length, 6 cm in breadth, and about 3 cm in anteroposterior thickness. In the adult male the weight of the kidney averages about 150 g., in the adult female 135 g. In a thin individual with a lax abdominal wall the lower pole of the kidney may just be felt in full inspiration by bimanual examination of the loin. Usually, however, it is impalpable.

RENAL SURFACE PROJECTIONS



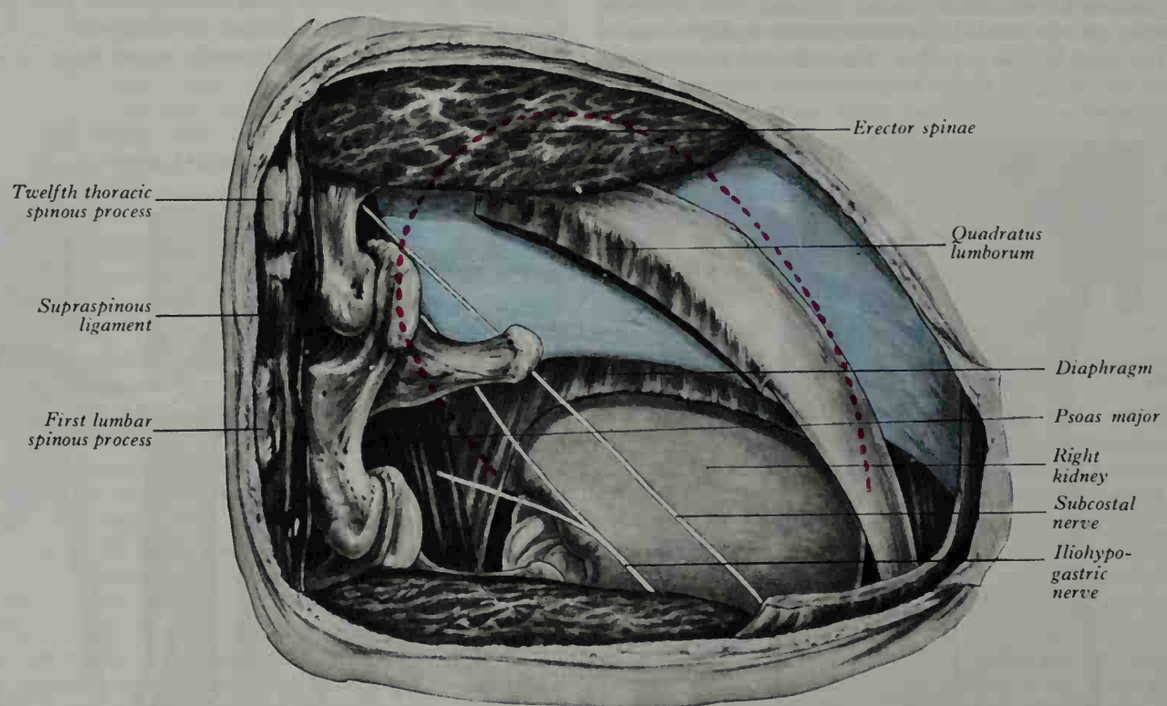
In the recumbent position, the outline of each kidney can be projected to the anterior or posterior surface of the abdominal wall as follows, bearing in mind that the right kidney is a little lower (about 1·25 cm) than the left. (*a*) *Anterior surface.* The centre of the hilum is approximately at the transpyloric plane, about 5 cm from the median plane and slightly medial to the tip of the ninth costal cartilage. The hilum of the left kidney is just above the transpyloric plane and that of the right kidney just below it (**8**.145). In relation to this position of the hilum, a kidney-shaped figure is drawn, 11 cm long and 4·5 cm broad, so that the upper pole is about 2·5 cm and the lower pole about 7·5 cm from the midline. (As the kidney lies obliquely, the width of the figure is about 1·5 cm less than the actual width of the organ.)

8.145 Surface projections of the duodenum, pancreas and kidneys. The lower ribs and the lumbar vertebrae are also indicated.

8.146 The anterior surfaces of the kidneys, showing the areas related to neighbouring viscera.

8.147 The posterior surfaces of the kidneys, showing the areas of relation to the posterior abdominal wall.

(*b*) *Posterior surface*. The centre of the hilum lies opposite the lower border of the spine of the first lumbar vertebra, about 5 cm from the median plane. In relation to this point, a figure is constructed in the same way as that described above for the anterior surface. The lower pole is usually a little (2·5 cm) above the highest part of the iliac crest. The kidneys lie about 2·5 cm lower in the standing than in the recumbent position and they move up and down with respiration.



RENAL RELATIONS

The *anterior surface* (**8**.111A, 146) is convex, and actually faces anterolaterally. Its relations to adjacent viscera differ on the two sides of the body.

(*a*) *Anterior surface of right kidney*. A small area of the superior pole is in contact with the right suprarenal gland, which may overlap it or the upper part of the medial border. A large area just below this and involving about three-fourths of the surface, lies in the renal impression on the right lobe of the liver, and a narrow area near the medial border is in contact with the descending part of the duodenum. Inferiorly the anterior surface is in contact laterally with the right colic flexure, and medially with part of the small intestine. The area in relation with the small intestine and almost the whole of the area in contact with the liver are covered with peritoneum (with the intervention of the renal fascia); the suprarenal, duodenal and colic areas are devoid of peritoneum.

(*b*) *Anterior surface of left kidney*. A small area along the superior pole of the medial border is in relation with the left suprarenal gland, and about the upper two-thirds of the lateral half of the anterior surface are in contact with the renal impression on the spleen. A somewhat quadrilateral field, about the middle of the anterior surface, is in contact with the body of the pancreas and the splenic vessels. Above this there is a small triangular region, between the suprarenal and splenic areas, which is in contact with the stomach. The size of the gastric area of contact is very variable. Below the pancreatic and splenic areas the lateral part is in relation with the left colic flexure and the commencement of the descending colon, and the medial part with the first coils of the jejunum. The jejunal area is extensive but the colic area forms an irregular, narrow strip immediately adjoining the lateral border of the kidney. The area adjacent to the stomach is covered with the peritoneum of the omental bursa, while the areas in relation to the spleen and the jejunum are covered with the peritoneum of the greater sac; behind the peritoneum of the jejunal area some branches of the left colic vessels are related to the kidney. The suprarenal, pancreatic and colic areas are devoid of peritoneum, because these organs are in actual contact with the kidney, without any possibility of mutual movements.

The *posterior surface* (**8**.147, 148, 150) is actually directed posteromedially. It is embedded in fat, and is devoid of peritoneal covering. It lies upon the diaphragm, the medial and lateral arcuate ligaments, the psoas major, the quadratus lumborum, and aponeurotic tendon of the transversus abdominis, the subcostal vessels, and the subcostal, iliohypogastric and ilio-inguinal nerves. The upper pole of the right kidney is level with the twelfth rib, that of the left with the eleventh and twelfth. The diaphragm separates the kidney from the pleura, which descends to form the costodiaphragmatic recess (**8**.148), but sometimes the muscular fibres of the diaphragm are defective or absent over a triangular area immediately above the lateral arcuate ligament; when this is so the perirenal adipose tissue is in contact with the diaphragmatic pleura.

8.148 The right kidney, posterior exposure. The blue area represents the pleura, the broken red line the upper part of the kidney. The subcostal nerve has been displaced downwards. Parts of the diaphragm and the quadratus lumborum have been resected.

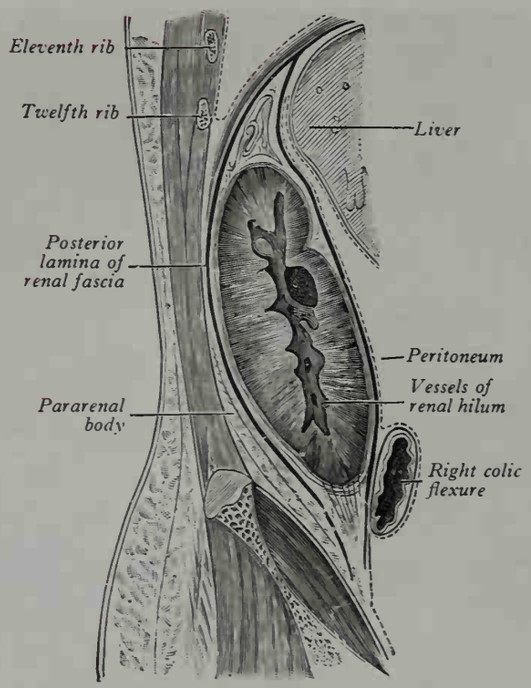
The *superior pole* of each kidney is thick and round, and is nearer the median plane than the lower; it is related to the suprarenal gland. The *inferior pole*, smaller and thinner than the upper, extends to within 2·5 cm of the iliac crest.

The *lateral border* is convex; that of the left kidney is covered superiorly with greater sac peritoneum which separates it from the spleen and, below this, it is in contact with the descending colon; the lateral border of the right kidney is separated by peritoneum of the greater sac from the right lobe of the liver.

The *medial border* of each kidney is convex adjacent to the poles and concave between these curvatures; it slopes downwards and laterally. In its central part there is a deep vertical fissure opening anteromedially, termed the *hilum*, which is bounded by an anterior and a posterior lip, and contains the renal vessels and nerves and the funnel-shaped continuation of the upper end of the ureter, the *renal pelvis*. The relative positions of the main hilar structures are as follows: the renal vein is in front, the renal artery in the middle and the pelvis of the kidney behind. Commonly one of the branches of the renal artery enters the hilum behind the renal pelvis, and it is not uncommon to find one of the tributaries of the renal vein issuing from the hilum in the same plane. Above the hilum the medial border is in relation with the suprarenal gland, and below with the commencement of the ureter.

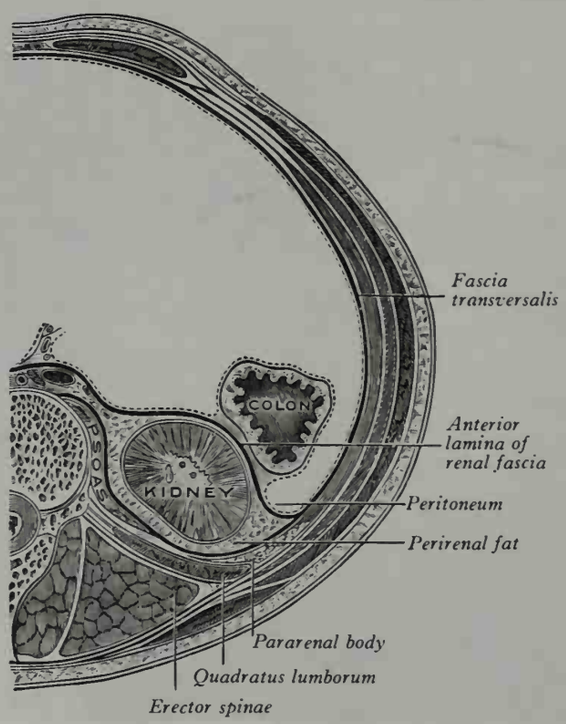
The hilum leads into a central recess named the *renal sinus*, which is lined by a continuation of the capsule of the kidney and is almost entirely filled by the pelvis of the kidney and renal vessels; numerous nipple-like elevations, termed the *renal papillae*, indent the wall of the sinus. The renal pelvis extends outside the hilum to become continuous with the ureter. Within the sinus it divides into two, sometimes three, large branches, which are named the *major calices*, and each of these divides again into several short branches, named the *minor calices* (**8**.149, 152). In all, there are usually from seven to thirteen of these minor calices; each expands as it approaches the wall of the renal sinus, and the expanded end is indented and moulded round from one to three renal papillae (**8**.149). The wall of the expanded end of each calix is firmly adherent to the capsule lining the renal sinus; it is perforated by the collecting tubules which open on the summits of the renal papillae.

The kidney and its vessels are embedded in a mass of adipose connective tissue, termed the *perirenal (perinephric) fat*, which is thickest at the borders of the kidney and is prolonged through the hilum into the renal sinus. The fibro-areolar tissue surrounding the kidney and perirenal fat is condensed to form a sheath termed the *renal fascia* (**8**.150A, B).



THE RENAL FASCIA

At the lateral border of the kidney the two layers of the renal fascia are fused. The anterior layer is carried medially in front of the kidney and its vessels, and at the level of the latter it merges with the connective tissue around the aorta and inferior vena cava. This medial continuation is very thin and does not extend higher than the superior mesenteric artery. The posterior layer extends medially behind the kidney and in front of the fascia on the quadratus lumborum and psoas major, and is attached to that fascia at the lateral and medial borders of the psoas, and to the vertebrae and intervertebral discs. There is also a deeper stratum (not shown in **8**.150) attaching the anterior and posterior layers to one another at the medial border of the kidney and pierced by the renal vessels (Martin 1942). This may account for the fact that a perirenal effusion of fluid does not usually extend across to the opposite perirenal space. However, injected air *does* diffuse along this route (Grossman 1954). Above the suprarenal gland the two layers of the renal fascia fuse, and are connected with the fascia of the diaphragm; it is generally agreed that below the kidney they remain separate, enclosing the ureter, the anterior layer being gradually lost in the extraperitoneal tissue of the iliac fossa, while the posterior layer blends with the fascia over the iliacus; but this has been denied (Mitchell 1950). The renal fascia is connected to the fibrous capsule of the kidney by numerous trabeculae, which traverse the perirenal fat, and are strongest near the lower pole. Behind the renal fascia there is a considerable quantity of fat, termed the *pararenal (paranephric) body*. The kidney is held in position partly through the attachments of the renal fascia, but principally by the apposition of the neighbouring viscera.



8.149 A left retrograde pyelogram. The contrast medium has been introduced into the calices, pelvis and upper ureter via a ureteric catheter, which is still in position, and can be clearly identified. There is considerably greater density of the shadows of the calices than that achieved by the intravenous method. Note the relation of the ureter to the tips of the lumbar transverse processes, and the characteristic 'cupping' or 'champagne glass' profiles of the tips of the lesser calices where they surround the renal pyramids. 'Calix' means a cup, and such 'cupping' of the minor calices is the normal appearance. (Note that the major calices are not cups and are hence inappropriately named.)

In the fetus the kidney consists of about twelve distinct lobules (**8**.151), but in the adult these are fused and the kidney presents a uniformly smooth surface, though traces of the fetal lobulation may remain.

8.150B A transverse section, showing the relations of the renal fascia.

GENERAL RENAL STRUCTURE (**8**.152A–D)

The kidney is invested by a thin capsule that is easily stripped off and consists of white fibrous tissue, with a few yellow elastic and nonstriated muscle fibres. In some diseases of the kidney the capsule becomes adherent to the kidney and cannot be easily stripped away.

The kidney has an internal *medulla* and an external *cortex*.

The *renal medulla* consists of a number of pale, striated, conical masses, termed the *renal pyramids*, the bases of which are directed towards the periphery of the kidney, while their apices converge towards the renal sinus, where they form prominent papillae projecting into the interior of the calices, each minor calix receiving from one to three papillae. Each pyramid, capped by cortical substance, forms a *'lobe'* of the kidney. Estimates of the number of papillae—and hence of pyramids or renal 'lobes'—are somewhat variable. In counts of them in 375 human kidneys (Lake *et al.* 1966), the range was 5 to 11 in 89 per cent with a most frequent value of 8 papillae (in 26 per cent). Total numbers of terminal uriniferous ducts (of Bellini) opening on the papillae varied (in each of 208 kidneys) from 116 to 776; no marked peak frequency was observed, but 23 per cent of the kidneys displayed in the region of 275 openings of uriniferous ducts. In another series of 54 kidneys (Arvis 1969), the number of papillae was 6 to 14.

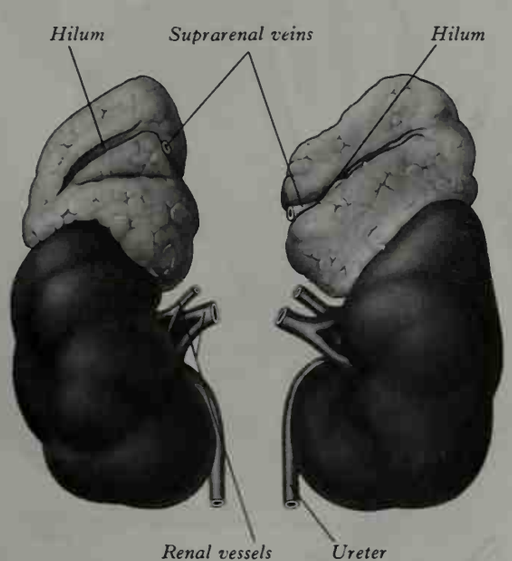
The *renal cortex* (**8**.152A) lies immediately beneath the fibrous capsule, arches over the bases of the pyramids, and dips in between adjacent pyramids towards the renal sinus. The parts dipping in between the pyramids are named the *renal columns* (**8**.152C), while the regions which connect the renal columns with each other and intervene between the bases of the pyramids and the fibrous capsule are called the *cortical arches* or *cortical lobules*. If this latter part of the cortex be examined with a lens, it will be seen to be traversed by a series of radially orientated lighter-coloured *medullary rays* (**8**.152C), and a darker-coloured intervening substance, which from the complexity of its structure is named the *convoluted part*. The rays gradually taper towards the capsule of the kidney, and consist of a series of outward prolongations from the base of each renal pyramid.

The cortex is also divisible into an *outer* and *inner zone* according to its histological organization. The inner cortex is divided from the medulla by a line of tangentially running blood vessels (the arcuate arteries and veins) although a thin layer of cortical tissue (the '*subcortex*') is present on the medullary side of this line. The layers of cortex close to the medulla are also termed the *juxtamedullary cortex* by some authors.

RENAL HISTOLOGY

The kidney is composed of a very large number of tortuous, closely packed *uriniferous tubules*, bound together by a little connective tissue in which run the blood vessels, lymphatics and nerves. Each uriniferous tubule consists of two parts, which are embryologically distinct (p. 210), namely (1) the *nephron* or secreting part, which elaborates the urine, and (2) a *collecting tubule*. The *nephron* comprises (*a*) the *renal corpuscle*, which is concerned with filtration of substances from the plasma; (*b*) the *renal tubule*, which is concerned with the selective resorption of substances from the glomerular filtrate until it approaches the composition of urine. The *collecting tubule* carries the fluid from a number of renal tubules to a terminal *papillary duct* or *duct of Bellini*; the latter opens into a minor calix at the apex of a renal papilla. If the surface of one of the papillae be examined with a lens, it will be seen to be studded over with numerous minute openings (*vide supra*), the orifices of the ducts of Bellini, and if pressure be made on a fresh kidney, urine will be seen to exude from these orifices.

THE RENAL CORPUSCLE (**8**.152D, 153A)



The renal (Malpighian) corpuscles, which are small rounded masses, averaging about 0·2 mm in diameter, are visible in the renal cortex and columns (of Bertin) except a narrow zone around the perimeter of the cortex (the *cortex corticis*). There are one to two million renal corpuscles in each kidney, the numbers falling with age (Dunnil and Halley 1973). Each of these bodies is composed of two parts: a central *glomerulus* of vessels, and a membranous envelope, termed the *glomerular capsule*, which is the small pouch-like commencement of a renal tubule.

The glomerulus is a lobulated tuft of convoluted, capillary blood vessels, held together by scanty connective tissue. This capillary network is derived from a small *afferent arteriole*, which enters the capsule, generally at a point opposite to that at which the latter is connected with the tubule; the *efferent arteriole* emerges from the capsule at the same point, which is thus known as the *vascular pole* of the capsule. The glomeruli have a simple form up to late prenatal life and, while some may maintain this form for about six months after birth, the majority of these mature by six years of age and all are of adult form by twelve years

(Macdonald and Emery 1959). In the fetal rabbit, guinea-pig and sheep the precursor of a glomerulus is a solid sphere of mesodermal cells in which vessels develop by canalization. The glomerulus comes to consist of a compact anastomosing plexus of vessels, and not of independent capillary loops, and the lobules of the glomerulus are not independent (Lewis 1958).

The glomerular capsule (of Bowman) is the blind, expanded end of the renal tubule, deeply invaginated by the glomerulus. Its lining consists of epithelial cells which are of the squamous type in its outer (parietal) wall; in contrast, surrounding the capillaries of the glomerulus (glomerular or visceral wall) are specialized, epithelial *podocytes* (Latta 1973; Spinelli 1974). Thus, between the glomerulus and the outer layer of the capsule there is a flattened cavity, the *urinary space*, which varies in size according to the secretory activity of the glomerulus (*vide infra*), and is continuous with the lumen of the proximal convoluted tubule. A distinct basal lamina underlies the cells of the capsule and, in the glomerulus, this fuses with the basal lamina surrounding the capillary endothelial cells. The podocytes which surround the capillary loops are highly distinctive, consisting of flattened stellate cells, the major dendrite-like processes of which are curved around the capillaries, interdigitating tightly with the processes of other podocytes. Where they approach neighbouring capillaries, many end-feet (pedicels), encroach on the basal lamina, leaving narrow gaps between them. Each podocyte contains numerous mitochondria, microtubules, microfilaments, and vesicles of various types, indicating a metabolically active state. The *endothelium* of the glomerulus is of the finely fenestrated type; the only barriers to the passage of fluid from the capillary lumen to the cavity of the glomerular capsule are therefore the fused basal laminae of the endothelium and podocytes. This layer, the *glomerular basement membrane*, is about 0·33 μm thick in man, and is finely fibrillar. The membrane is composed of three distinct layers, the first and third of which are pale-staining (the *laminae rarae interna* and *externa*) and the middle one dense and fibrous (the *lamina densa*). Unlike many fenestrated endothelia, there does not appear to be a regular dense lamina across the pores of the glomerular endothelial cells, but on the distal margin of the glomerular membrane the area between adjacent podocyte end-feet is covered by a clear dense layer, *the glomerular slit diaphragm*, through which the filtrate must pass before it enters the urinary space. This diaphragm has recently been shown to be made of fine filaments arranged in two highly regular rows looking rather like a zip-fastener (Rodewald and Karnovsky 1974) which may be significant in forming a further sieve in the glomerular filter. Much evidence indicates that the glomerular basement membrane acts as a selective filter, allowing the passage from the blood, under pressure, of water and a variety of the smaller types of molecule present in the circulation. Molecules such as haemoglobin are able to pass through, but larger molecules are held back. The selectivity of this process appears to be related to the physical and chemical characteristics of the glomerular filter. Tracer experiments show that some of the material withheld from the urine by the glomerulus passes through all but the outer surface of the filter, which therefore acts in a much more complex fashion than would a simple physical filter (Rennke *et al.* 1975).

In addition to the cell types mentioned above, irregular *mesangial cells* with phagocytic and contractile capacities have been demonstrated, particularly around the base of the glomerular capillary tufts. The mesangial cells are important in clearing the glomerular filter of enmeshed substances which may otherwise clog it; for example, immune complexes, cellular debris, etc. (*see* Caulfield and Farquhar 1974).

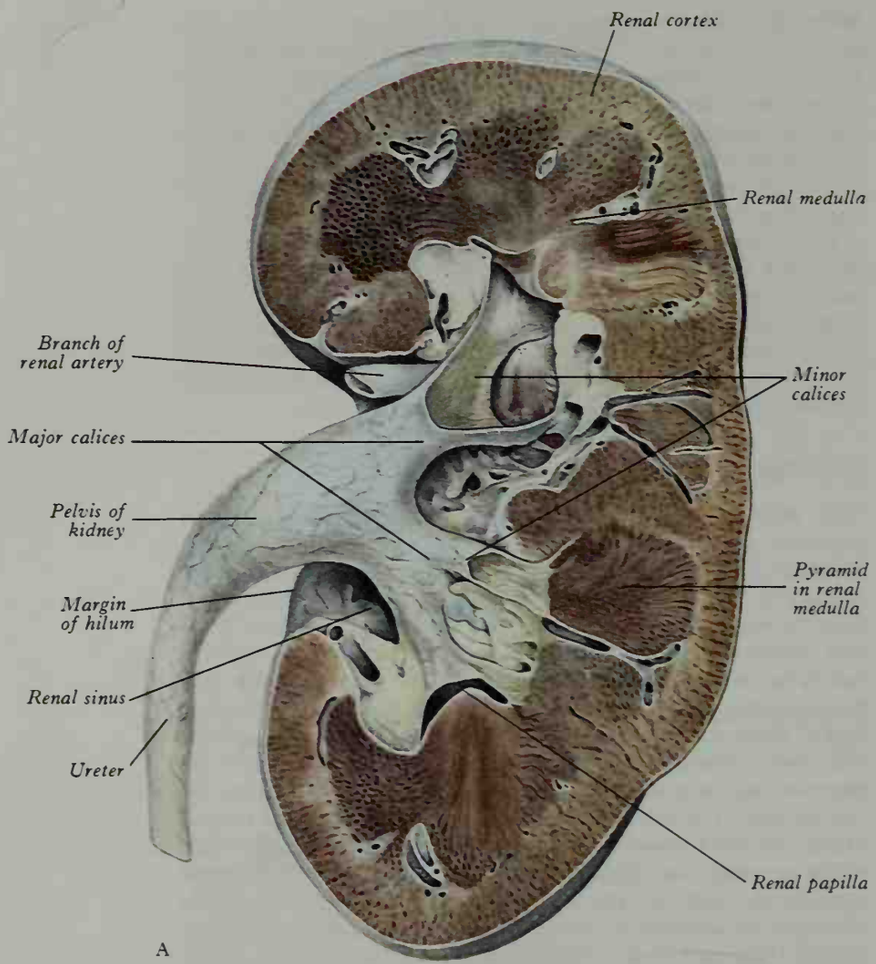
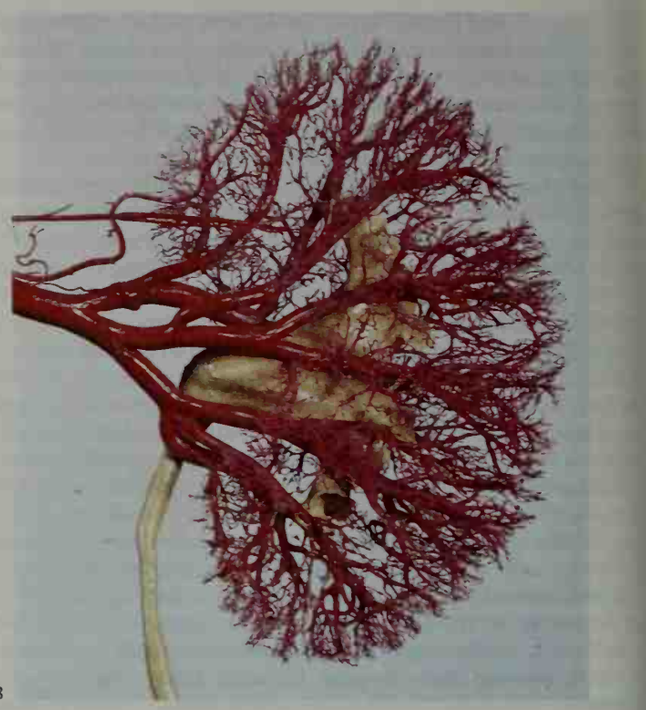
THE RENAL TUBULE

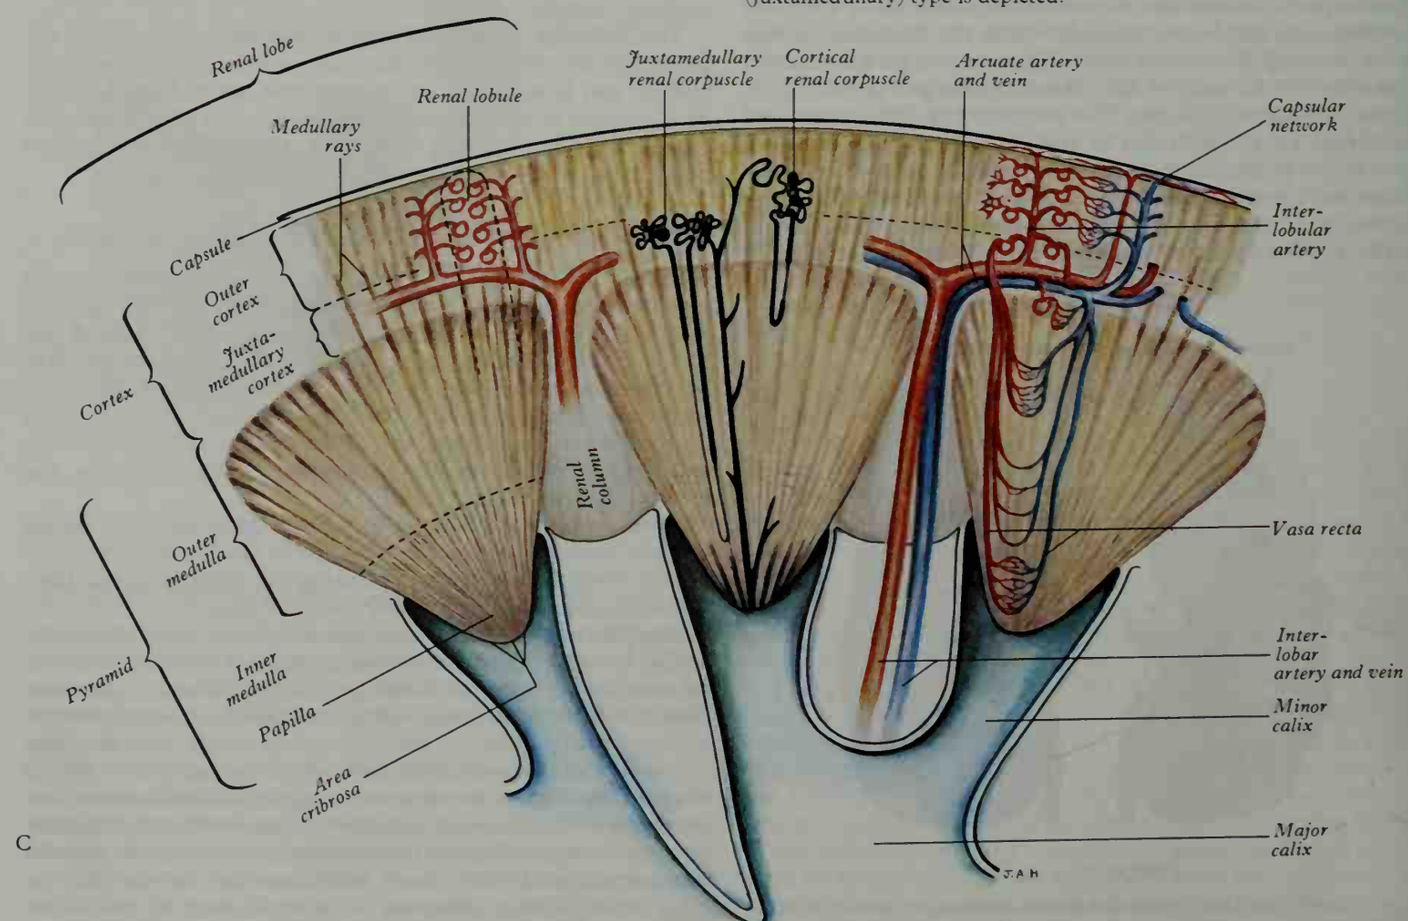


Each renal tubule (**8**.152D) consists of the following parts in sequence: (1) the *glomerular capsule*, already described; (2) the *proximal* (or first) *convoluted tubule*, connected to the glomerular capsule by a short *neck* (which in man is only slightly narrower than the rest of the tubule); the initial part forms a series of loops (the *convoluted portion*), while the terminal part of the proximal tubule becomes straight or slightly spiral (the *straight portion*) and runs towards the medulla to become (3) the *descending limb* of the *loop of Henle* connected by (4) a 'U' turn to (5) the *ascending limb*. The descending and ascending limbs of the loop of Henle may be narrower and thin-walled along much of their length, forming the *thin segment*. The upper part of the ascending limb of the loop of Henle (the *thick segment*), however, has a diameter similar to that of the proximal convoluted tubule. The ascending limb becomes continuous with (6) the *distal* (or *second*) *convoluted tubule*, divisible into a *straight* and a *convoluted section*, between which is a special thickened region, the *macula densa*; the nephron finally straightening out as (7) the *junctional* or *connecting tubule*, which ends by joining (8) a *collecting* or *straight duct*. Between the distal convoluted tubule and the junctional tubule, there is often a short angular segment of the renal tubule that is called the *zigzag* (or *irregular*) *tubule*.

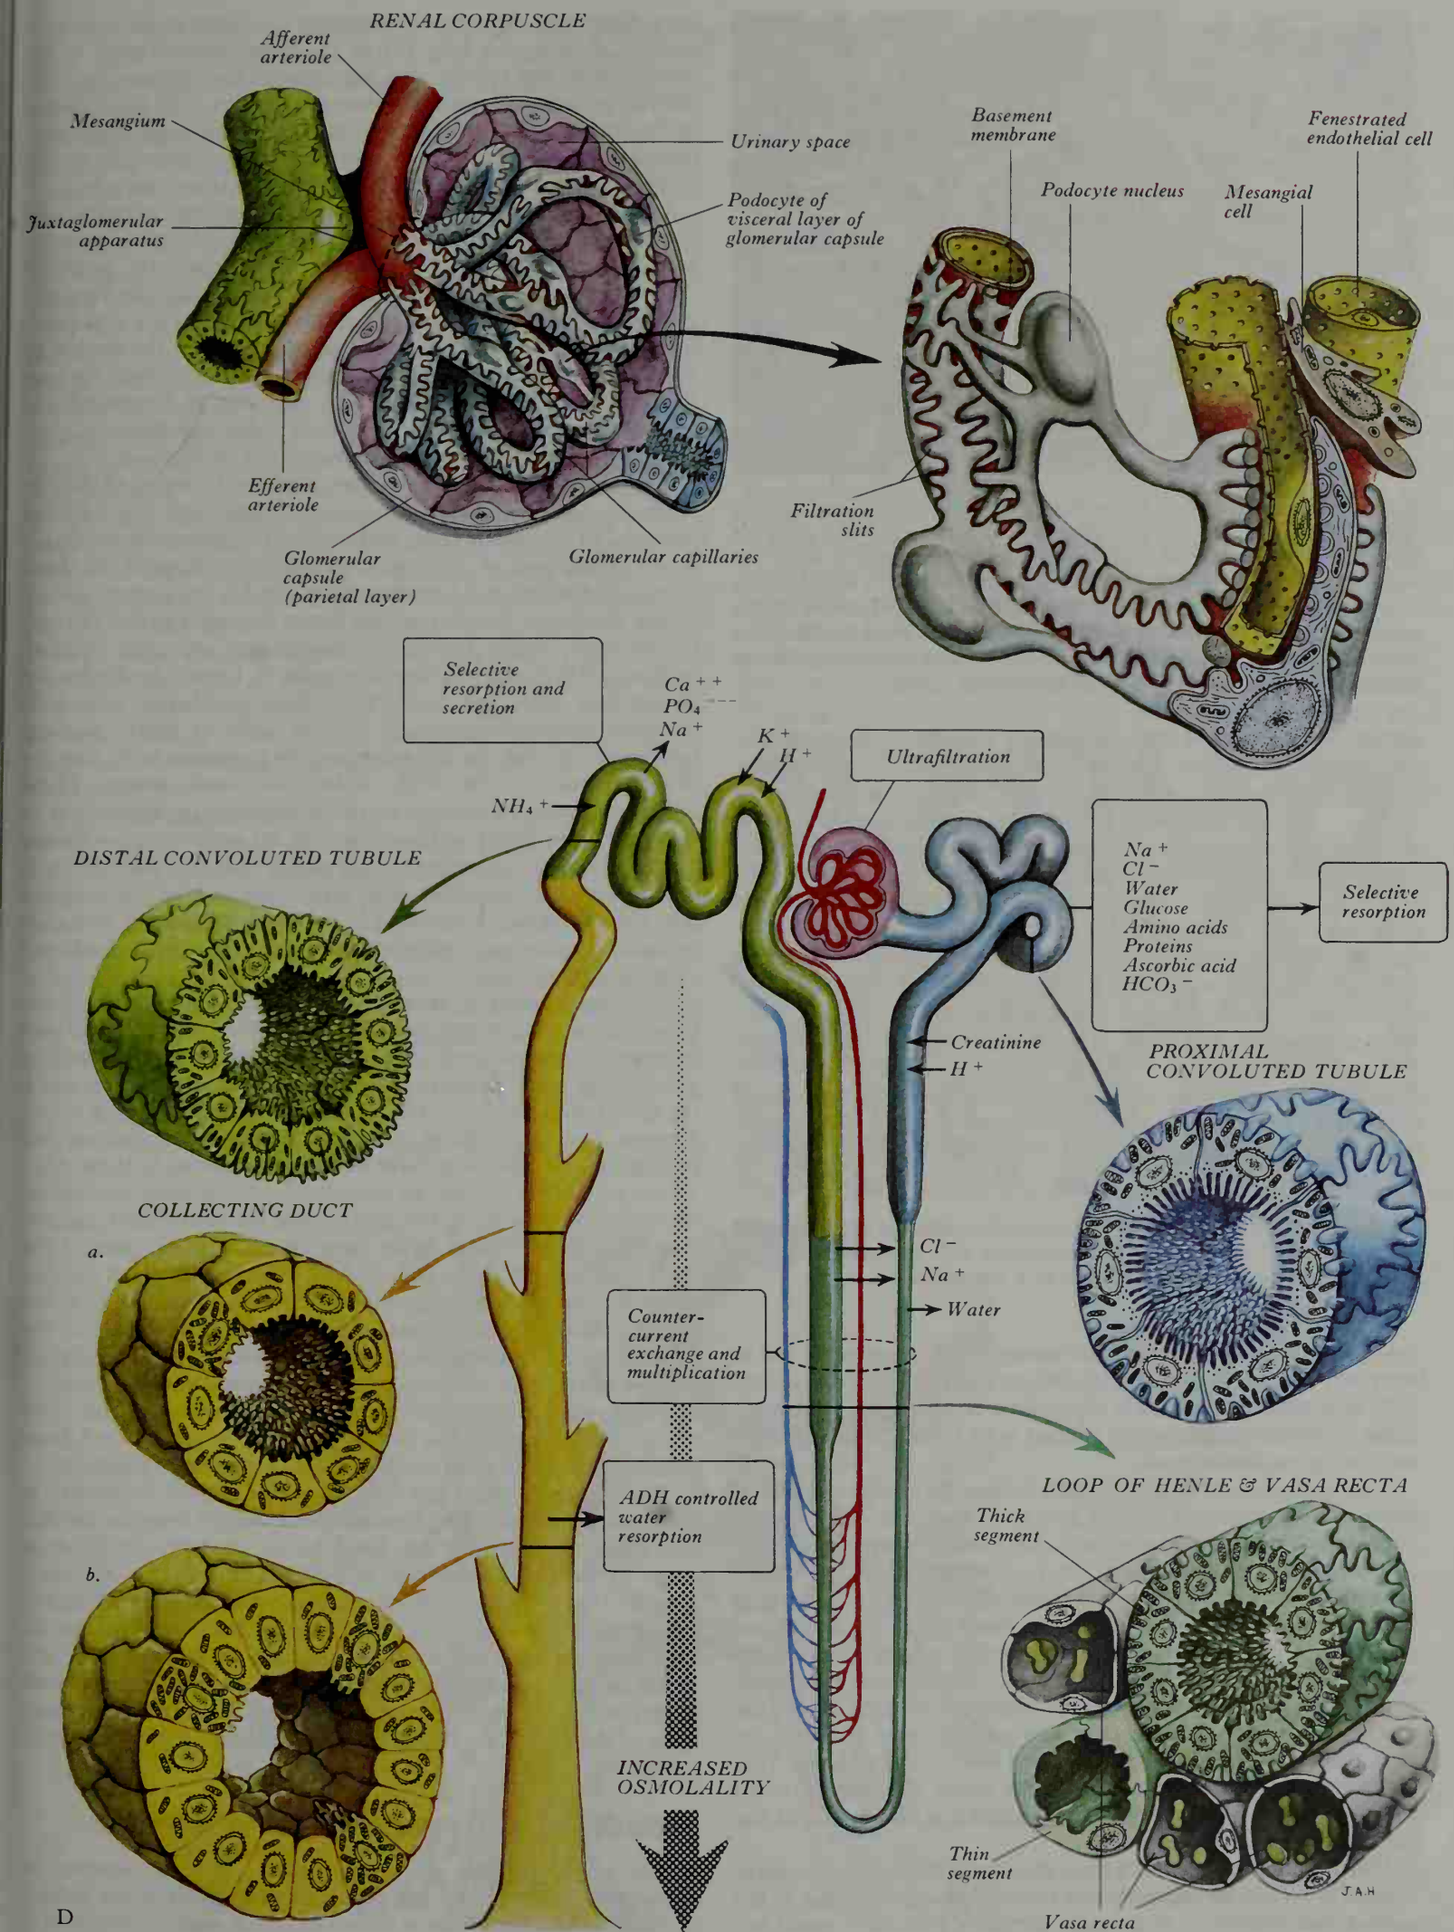


The *collecting* (or *straight*) ducts (**8**.154B) commence in the medullary rays of the cortex; they unite at short intervals with one another and finally open into wider tubes, termed the *papillary ducts* or *ducts of Bellini*, which in turn open on the summit of a papilla, the numerous duct openings giving the tip of the papilla a perforated, cribriform, appearance (*area cribrosa*).

STRUCTURE OF THE RENAL TUBULE (**8**.152D, 153A)



The renal tubules are lined by a single layer of epithelial cells outside which is a basal lamina of varying thickness (Maunsbach 1973). The precise form of the constituent cells varies from one part of the tubule to another, according to their distinctive roles in the functioning of the kidney. These cells are concerned with the active transport and passive diffusion of various ions and water into and out of the tubules, and with the removal of any proteins and certain other organic substances which may pass the glomerular filter (Bulger 1977).



The proximal tubule is lined by cuboidal epithelial cells bearing a brush border of tall microvilli at their luminal surfaces. The precise shape of these cells depends on the pressure of the fluid within the tubule; in life this distends the lumen and stretches the lining cells to a slightly flattened cuboidal shape, which changes to a taller form when the glomerular blood pressure falls at death or on removal of tissue for histology. The cytoplasm of proximal tubule cells is strongly eosinophilic, and the nucleus euchromatic and centrally positioned. Faint striae are visible with the light microscope at the bases of the cells, which on inspection with the electron microscope are seen to be highly folded in a complex series of pleats between which lie numerous mitochondria orientated perpendicular to the basal lamina of the tubule. Careful reconstruction of these basal infoldings has shown that the complex of cellular processes is really formed by the inter-digitations between the lateral margins of adjacent epithelial

cells, thus creating a labyrinthine meshwork of cytoplasmic feet in the outer part of the tubule wall (Bulger 1965, 1977). As the same cells bear microvilli on their luminal faces, they have very large areas of plasma membrane in contact with both the tubular fluid and the extratubular space.

This arrangement is undoubtedly connected with the ability of these cells to transport various ions and small molecules against very steep concentration gradients, the energy being provided by the abundant mitochondria. It is interesting that sodium/potassium-stimulated adenosine triphosphatase has been located in both apical and basal membranes of these cells (Wachstein and Bradshaw 1965) and that numerous other enzymes associated with ionic transport have also been demonstrated in their cytoplasm. Apart from the active transport of ions across the epithelial cells, water and other ions can also pass between the cells passively, following osmotic and electrical gradients. It is probable that the passive movements occur through pervious tight junctions which have been described at the apices of the tubule cells (*see* Frömter 1979).

Other notable organelles within these cells include an extensive system of endocytic channels and lysosomes which engage in the uptake and hydrolysis of proteins normally passing in small but significant amounts into the glomerular filtrate (Caulfield and Farquhar 1975). Peroxisomes and lipid droplets are also frequently seen, and, at the base of each cell, a system of microfilaments, probably maintaining the shape of the tubule, is present. Among the long list of enzymes demonstrated in the cytoplasm of the tubule cells are cytochrome oxidase, succinic dehydrogenase and other respiratory enzymes, acid phosphatase in the lysosomes, glucose-6-phosphatase and leucine aminopeptidase; the high activities of these enzymes reflects the highly energetic nature of these cells in kidney function (*vide infra*).

Variations occur in cell structure, enzyme activity and functions of the proximal tubule cells. The initial region, or *neck* is very short and consists of the simple squamous epithelial extension of the outer wall of the renal corpuscle; the proximal tubule beyond this has been subdivided into three (or sometimes four) regions, the first typified by long microvilli, the second by microvilli of medium length, the third, again (in man) by long microvilli (*see* Moffat 1975). The patterns of lysosomal and transport activities appear to follow these subdivisions, too, although their functional importance is not understood.

The loop of Henle (renal loop, ansa nephroni) consists of the thin segment, narrow in diameter (about 30 μm) and lined by low cuboidal to squamous cells; and the thick segment (about 60 μm across) composed of cuboidal cells similar to those of the distal tubule with which it is sometimes classified as the *straight portion* of that structure. *The thin segment* forms the major part of the loop in the more deeply placed (juxtamedullary and deep cortical) nephrons which reach far into the medulla. In such nephrons, the descending limb has moderately thick epithelial cells with complex interdigitations and narrow belts of tight junctions between cells, whereas the ascending limb appears to be lined by thin squamous cells with wider junctional zones. These differences may be related to the distinctive permeabilities to water and ions found in these two tubular structures (*see* Bulger 1971). Very few organelles are present in either of the cell types, indicating a passive rather than active role in ionic movements. *The thick segment* is composed of cuboidal epithelium with cells containing numerous mitochondria, deep basolateral folds and short apical microvilli.

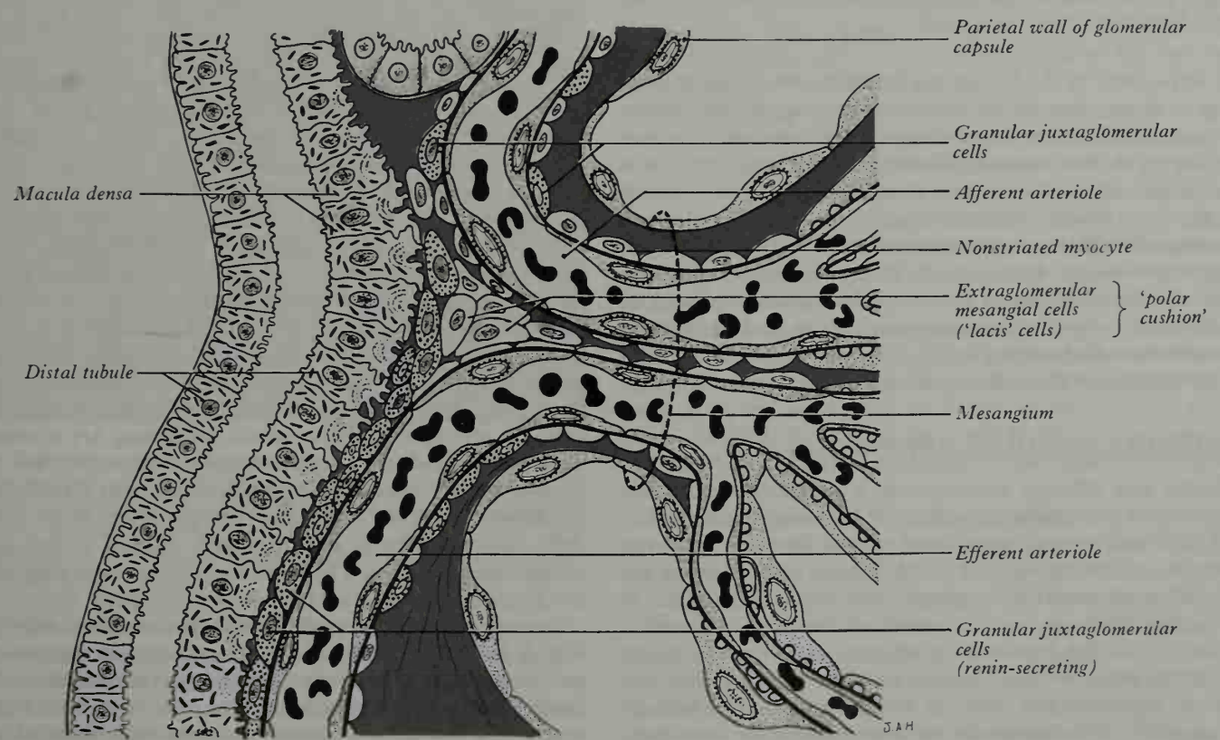
The distal tubule is lined by cells resembling those of the proximal tubule, except that the microvilli are few, small and irregularly spaced, and that the basolateral folds containing mitochondria are so deep and extensive that they almost reach the apical surfaces of the cells, as seen in vertical section (**8.152D**). Various enzymes related to active transport of sodium and potassium and other ions have been demonstrated in these cells, which are known to play an important part in ionic regulation. At the junction between the straight and the convoluted regions, the distal tubule comes to lie close to the vascular pole of the renal corpuscle, and the tubule cells form a specialized sensory structure, the *macula densa*, important in the regulation of blood flow and ionic exchange (*vide infra*). At the termination of the distal tubule the epithelium has fewer basal folds and sparser mitochondria, the tubule here sometimes being termed a *connecting duct*, since it has several characteristics of the more distal collecting duct, but unlike the latter is still formed from nephrogenic rather than ductual tissue during embryogenesis.

The collecting ducts are composed of simple cuboidal to columnar epithelium which progresses in height from the cortical end where they receive the distal tubule contents, to the wide ducts of Bellini, discharging at the area cribrosa on the renal papilla. These cells have relatively few organelles or lateral convolutions between cells, and bear only occasional microvilli. However, scattered among these cells are other, *dark cells*, also found in smaller numbers in the distal convoluted tubule, with longer microvilli and more numerous mitochondria. The functions of these cells are not yet known, although their presence is intriguing.

STRUCTURE AND FUNCTION IN THE NEPHRON

In the nephron three distinct processes operate together to determine the excretory and regulatory functions of the kidney (**8.152D**). The first of these is *filtration*, which occurs at the level of the glomerulus; the second is *selective resorption* of various materials from the filtrate as it passes along the nephric tubule; and the third involves *secretion* of various substances into the

filtrate by the cells of the tubule. The first two of these processes have been the more intensively studied, and more clearly correlated with the cytological structure of the nephron in its various regions.



Glomerular filtration is the term used to describe the passage of water, containing a wide variety of small molecules, from the blood into the urinary space of the glomerular capsule, the larger molecules such as those of the plasma proteins, polysaccharides and lipids being substantially retained in the circulation as though by a physical filter of minute pore-size placed between the blood and the lumen of the capsule. Such a filter exists in the glomerular basement membrane (see above for details of this, and of the fate of the small quantities of protein which pass through the filter).

Filtration occurs along the considerable pressure gradient existing between the inside of the large capillaries and the urinary space, across the glomerular basement membrane, which is the only structure separating the two. This pressure gradient is far greater than the osmotic gradient related to the colloid osmotic pressure of the blood, which tends to oppose the outward flow of filtrate. In the peripheral parts of the renal cortex, the arteriolar pressure gradient is enhanced by the dimensional inequality of the afferent and efferent arterioles of the glomerulus, the former having a larger diameter than the latter (*vide infra*). Further, in all glomeruli, the rate of filtration can be altered by vasomotor responses of the glomerular arterioles. When first formed, the *glomerular filtrate* is isotonic with the blood of the glomerulus, its composition also being identical in its concentration of ions and small molecules.

Selective resportion of many materials actively from the filtrate occurs mainly in the proximal convoluted tubule, particularly of glucose, amino acids, phosphate, chloride, sodium, calcium and bicarbonate. The proximal tubular cells are freely permeable to water, which moves from the tubule lumen along the osmotic gradient created by the resorption of these various solutes, so that the filtrate in this region remains isotonic with the blood. The numerous microvilli, folded lateral and basal surfaces, and profusion of mitochondria, indicate an active role in absorption by the proximal tubule cells. Further selective absorption, particularly of sodium ions, also occurs in the distal convoluted tubule.

The remainder of the renal tubule appears to provide a mechanism for the resorption of the great majority (95 per cent) of the water content of the glomerular filtrate, so that when it reaches the calices of the kidney, the urine has a greatly diminished volume, and is *hypertonic* to blood. Along the *descending* limb of the loop of Henle, sodium and water pass freely between the lumen of the tubule and the surrounding extratubular spaces of the renal medulla, which many loops occupy. In at least part of the *ascending* limb, chloride ions are actively transported from the lumen to the interstitial spaces and sodium ions follow passively, but in this tubular region the lining cells do not allow water to follow the sodium. Some of this sodium now diffuses back into the descending limb, being added to that already present in the filtrate passing along it; in the ascending limb, sodium is again extracted from this enriched solution, being added to the intercellular ions and again diffusing into the descending limb. Alternatively, sodium may not actually enter the descending limb, but water is merely withdrawn because of the raised tonicity of the extratubular fluid-filled space, thus concentrating the filtrate. In either manner, considerable concentrations of sodium and chloride ions are built up in the renal medulla, the responsible mechanism being termed a *countercurrent multipler system*. The potentially rapid removal of ions from the renal medulla by the circulatory system is minimized by another looped *countercurrent exchange system*. In the latter, the arterioles entering the medulla pass for long distances parallel to the venules leaving it, before breaking up into capillary beds around the tubules; this arrangement allows the passage of ions by diffusion from the outflowing to the inflowing blood, so that these vessels (the arteriolar and venular *vasa recta*) conserve the high osmotic pressure of the medulla as a whole.

Because of the selective extrusion of sodium and chloride by the cells of the ascending limb and distal tubule (under aldosterone control), the filtrate, when it reaches the distal end of the convoluted tubules, is *hypotonic* to the blood. However, as it passes on into the collecting ducts which descend again through the medulla, it moves into a region of high osmotic pressure and, since the cells composing the duct walls are, under the action of the antidiuretic hormone (ADH) from the neurohypophysis, variably permeable to water, the latter passes along the osmotic gradient into the neighbouring extratubular spaces (Gottschalk and Mylle 1959). Thus, throughout the collecting duct, the tonicity of the urine gradually rises, until at the renal pyramids it

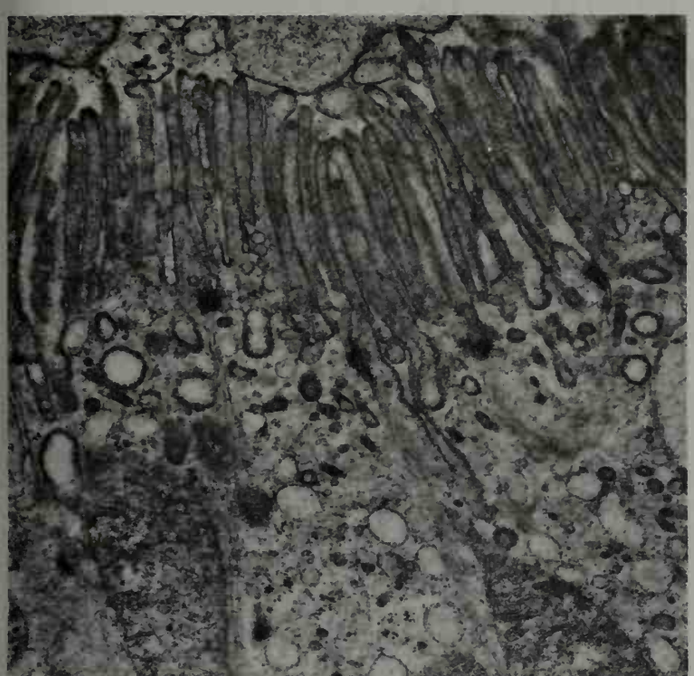
is finally *hypertonic* to the blood. In this manner, as mentioned above, up to 95 per cent of the water in the original glomerular filtrate is resorbed into the bloodstream. This complex system of controls is a highly flexible one, allowing considerable variations in filtration and absorption rates, depending upon the overall needs of the body at any particular time.

Secretion of various ions occurs at a number of sites, hydrogen ions and ammonium being particularly important in the regulation of acids and bases in the blood. Many other substances are also secreted, including various organic acids, and antibiotics, when administered therapeutically. The proximal and distal tubules are the chief regions carrying out these activities (**8**.152D).



THE JUXTAGLOMERULAR APPARATUS

The afferent and efferent arterioles of a glomerulus join the vascular pole of a glomerular capsule more or less opposite the site of origin of the proximal convoluted tubule (**8**.152D). In each nephron, the ascending limb of Henle's loop returns from the medulla and passes towards the glomerulus which gives origin to that particular nephron, and the commencement of the distal convoluted tubule lies between the afferent and efferent vessels at the vascular pole, in close contact with the vascular pole and the external aspect of the walls of the arterioles. The cells of the tunica media of the arterioles in this region differ from non-striated muscle cells of blood vessels in general in that they are large, rounded and 'epithelioid' in type and have large spherical nuclei; as revealed by special stains, their cytoplasm is granular. These cells are known as *juxtaglomerular cells* and they lie in close contact with the cells of the slightly dilated distal convoluted tubule, which are closely aggregated together in this region, forming the *macula densa*; these two groups of cells, together with various mesangial elements, constitute the *juxtaglomerular apparatus* of the kidney (Edelman and Hartroft 1961; Barajas 1966; Dalton and Hagenau 1967; Hartroft 1968). Ultrastructurally, the juxtaglomerular cells possess bundles of cytoplasmic fibrils, a prominent granular endoplasmic reticulum and Golgi complex, and numerous dense, membrane-bound secretory granules, which mature in association with the Golgi complex, and which vary in shape from spheroid, through ellipsoid, to rhomboid, according to the species (Barajas 1971). In many animals, interspersed between the foregoing, are other so-called '*lacis cells*', which are ultrastructurally similar, but lack granules. Cells of the macula densa approach a columnar form, with a paler cytoplasm and fewer organelles than elsewhere in the tubule, and their external aspects are intimately related to the surface of juxtaglomerular cells. The latter receive an innervation from non-myelinated nerve fibres which are adrenergic in type.

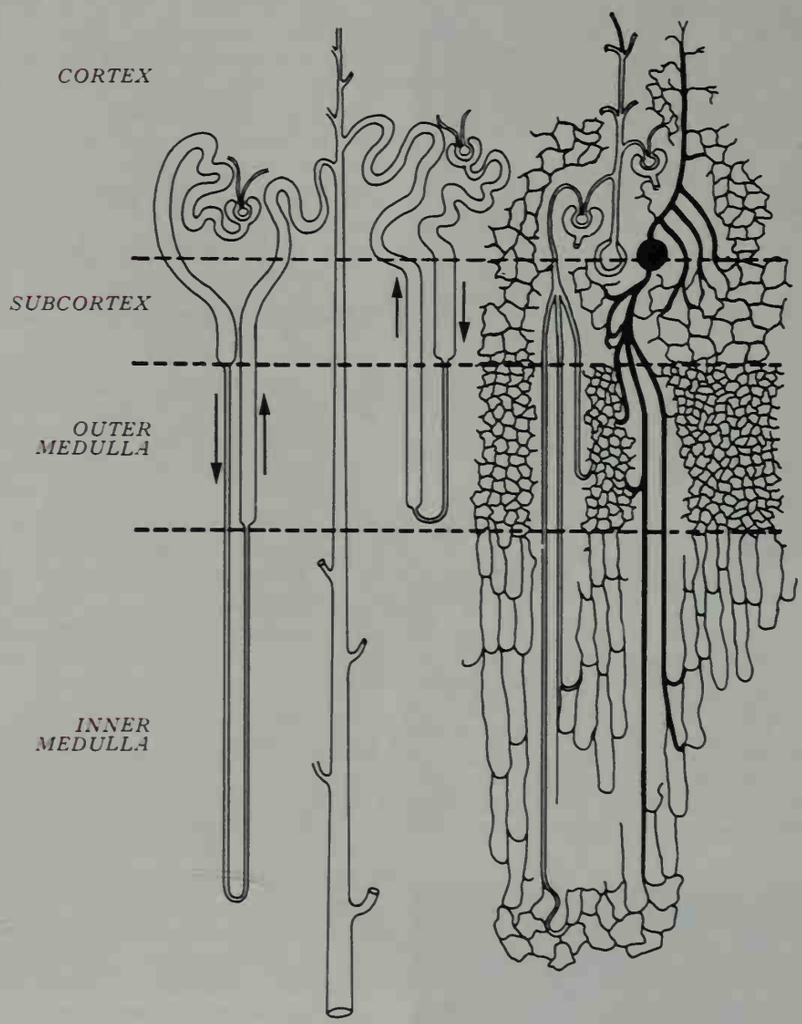
In experimental animals in which the blood supply to the kidney has been diminished, with consequent increase of blood pressure, and in some patients with hypertension associated with kidney disease, the juxtaglomerular cells have been found to be hypertrophied and to contain increased numbers of granules. These granules contain *renin*, an enzyme which converts a polypeptide in the blood, *angiotensinogen*, to *angiotensin I*; this in turn is converted, notably in the lung, by other enzymes into

8.155B A high-power electron micrograph of part of a glomerular capillary in a canine renal corpuscle to show, in greater detail, the structures intervening between the blood-vascular and urinary spaces. The capillary lumen (top centre) is bounded to the left by the nucleated part of an endothelial cell, and below by the thin cytoplasmic extension from a neighbouring endothelial cell, in which a few fenestrations are present. The urinary capsular space (below), the podocyte processes, and the compound glomerular basement membrane, which shows zonal variations in electron-opacity, may be identified. Magnification × 18,000.

8.155C A high-power electron micrograph of the apical (luminal) parts of four proximal convoluted tubular epithelial cells. The apical array of microvilli, subapical junctional complexes between adjacent cells, and the highly active cytoplasm containing lysosomes, parts of very large mitochondria, and a wide variety of granules, vesicles and vacuoles, are visible. Magnification × 20,000.

angiotensin II, a polypeptide with a wide variety of actions on the body, including the elevation of blood pressure and the stimulation of aldosterone release from the adrenal cortex (leading to more active removal of sodium ions from the distal convoluted tubule). The details of this system of renin secretion and consequent change in tubule activity are not yet clear, but the juxtaglomerular apparatus appears to provide an important feedback control regulating the flow of fluid through the glomerular filter, ionic resorption in the nephric tubule, and thus the final concentration of urine. There is evidence that renin secretion is controlled by at least three major factors (Davies and Freeman 1976): (1) the influence of the cells of the macula densa which react to changes in fluid passing them through the distal tubule; (2) the pressure of blood in the glomerular arterioles which in some way affects the secretory activity of the granule cells in their walls; (3) stimulation by the numerous sympathetic fibres ending close to the juxtaglomerular cells. These and other agents appear to enable the juxtaglomerular apparatus to correlate various aspects of blood flow, filtration rate and osmoregulation and to mediate appropriate action to maintain homeostasis.

OTHER CELLS IN THE KIDNEY



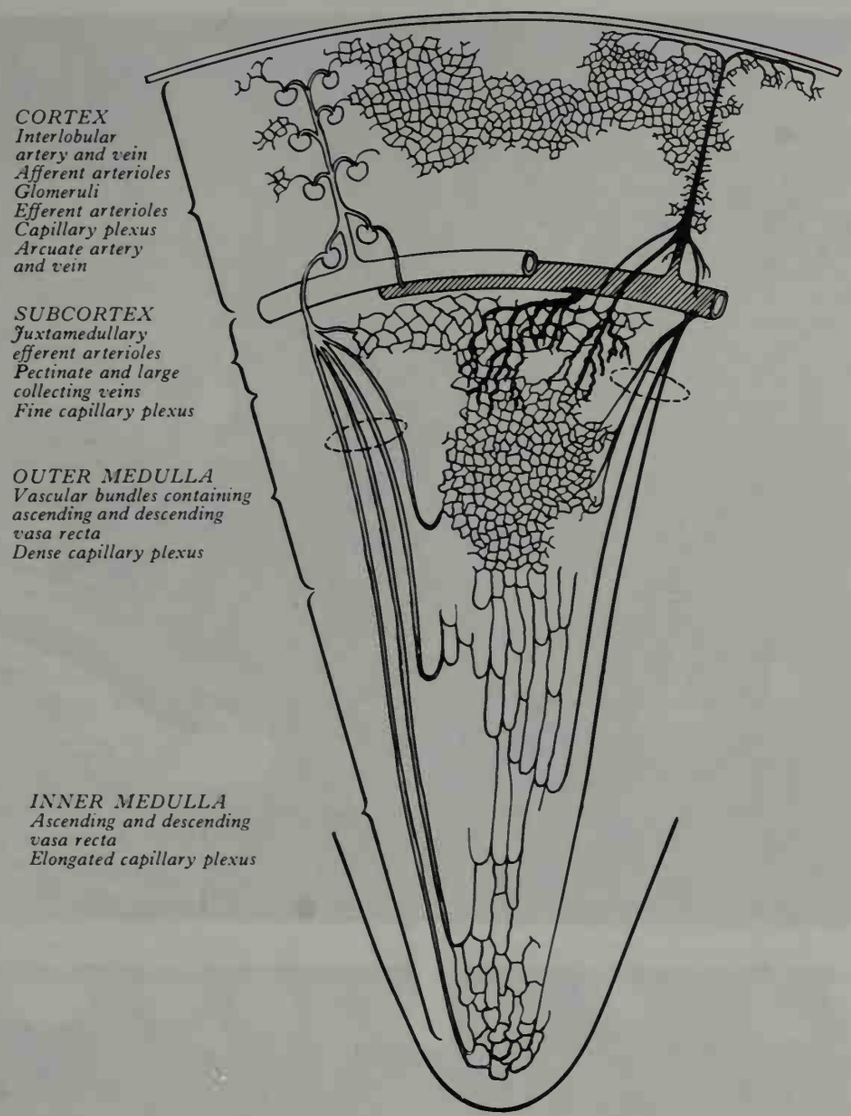
Between the renal tubules and blood vessels lie various cellular elements important to the structure and activities of the kidney. Amongst these are connective tissue elements, inconspicuous though present in the cortex, but prominent in the medulla, where they secrete the glycoprotein matrix, particularly in the papillary regions. The medullary *interstitial cells*, some of which at least, appear to be modified fibroblasts, form vertical piles of tangentially orientated cells between the more distal collecting ducts, giving a distinctive ladder-like appearance. Various studies have shown that these cells are able to secrete prostaglandins with widespread effects on visceral muscle and other cells in the body (Muirhead *et al.* 1972), although the significance of this finding is not yet clear.

RENAL BLOOD VESSELS

The complicated vascular patterns of the kidney show considerable regional specialization, and are closely moulded to the geometric organization and functional roles of the renal corpuscles, tubules and collecting ducts (**8**.152, 156, 157). A very large research literature has accumulated concerning not only renal angioarchitecture, but also renal haemodynamics, and the control factors which may operate to secure appropriate functional variations in blood flow. Analysis of this must, however, be omitted here; similarly, no attempt will be made to describe the important species variations in pattern known to exist, or the minor variations in the human pattern. For these considerations, and as an introduction to the literature, the interested reader should consult works devoted exclusively to these topics, for example Trueta *et al.* (1947) published over thirty years ago, and the admirable reviews by Fourman and Moffat (1971), and Moffat (1975).

The renal vasculature may, of course, be studied at various levels of organization, commencing with the origin, course, structure, variations and primary branches of the principal *renal artery*, and the disposition of any *accessory renal arteries* which may also be present. Together with the primary patterns of branching, and their substantial areas of distribution, may be considered the concept of *vascular segmentation* of the kidney. Arising sequentially from these primary branches are *lobar*, *interlobar*, *arcuate* and *interlobular* arteries, the *afferent* and *efferent glomerular arterioles*, the cortical *intertubular capillary plexuses*, and the venous radicles which drain these regions; the *vasa recta* and associated capillary plexuses which supply the renal medulla must also be considered. (The disposition of the vessels and their relationship to the uriniferous tubules are summarized in **8**.152, 156.)

The main features of the origins, courses and extrarenal distribution of the *renal arteries* have already been described (p. 718). Single arteries on right and left sides occur in about 70 per cent of individuals, but they vary somewhat on the two sides and in different individuals, in terms of their level of origin (the right often being superior), their calibre, obliquity and precise topographic relationships. (For a most extensive review of this clinically important topic in almost 11,000 kidneys, *see* Merklin and Michels 1958.) In its extrarenal course (Schneider *et al.* 1969) each renal artery gives off one or more inferior suprarenal arteries, and rami of supply to the perinephric tissue, renal capsule, pelvis and proximal part of the ureter; and upon or just before reaching



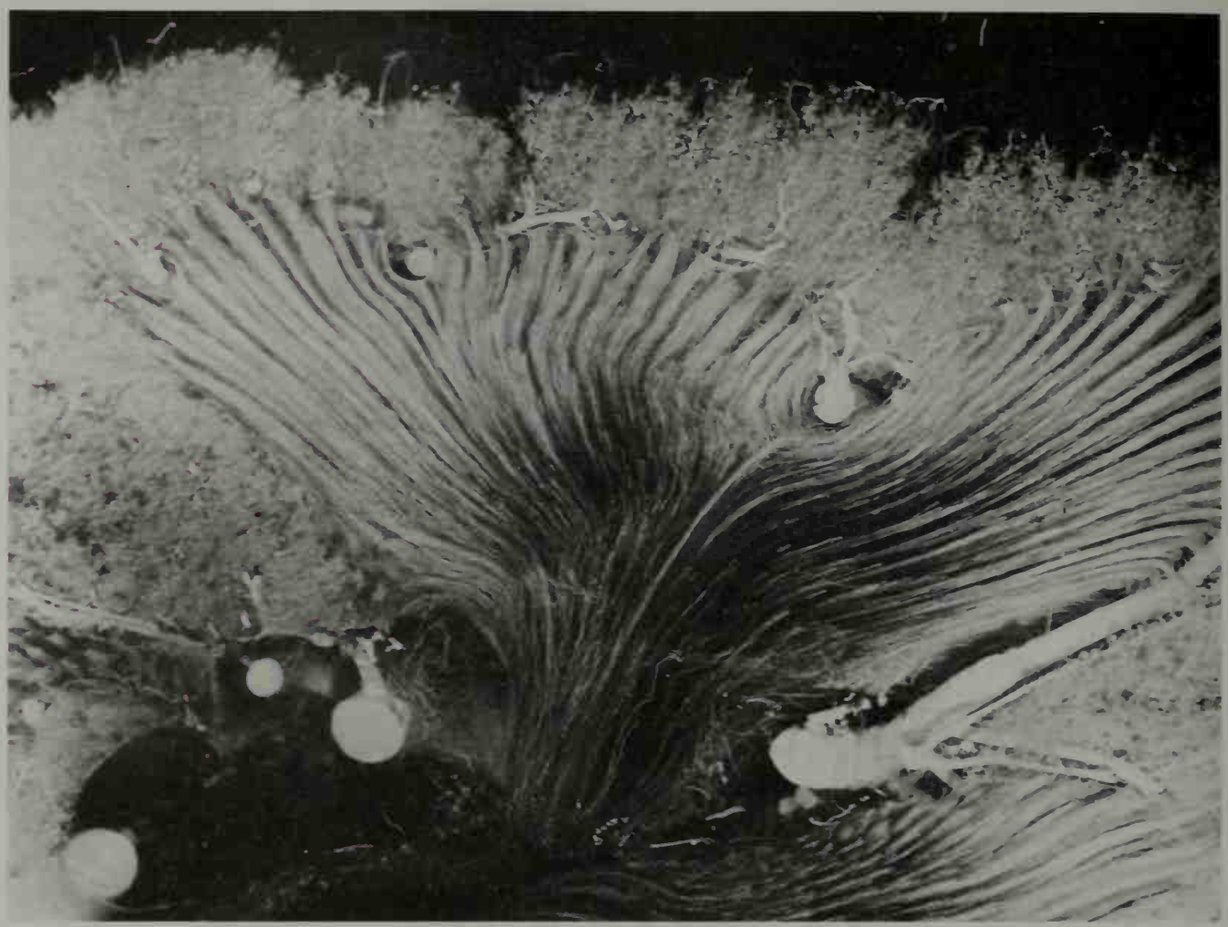
8.156A A diagram to illustrate the arrangement of the tubules (left) and blood vessels (right) in various structural zones of the kidney. Note the variations in the pattern of the tubules with either long or short medullary loops; tubules of intermediate length also occur. Compare the different structural and functional segments of the tubules which occur together in the cortical, subcortical, and outer and inner medullary zones, with their related vascular patterns. Arteries—black outlines; capillaries—single black lines; veins—full black. Compare with **8**.156B. (From *the Blood Vessels of the Kidney*, by Julia Fourman and D. B. Moffat, by courtesy of the authors and publishers, Blackwell Scientific Publications, Oxford, 1971.)

the hilum of the kidney, the renal artery on each side divides into an *anterior* and a *posterior division*. The primary branches of the divisions (the *segmental arteries*) supply the *vascular segments* of the kidney.

Accessory renal arteries are common, occurring in up to 30 per cent of individuals. Usually such arteries arise from the aorta, above or below the renal artery, and pursue a course parallel with it to the renal hilum. Higher or lower origins are, however, not uncommon, the accessory artery or leash of arteries passing to the superior or inferior pole of the kidney. The foregoing are widely regarded as members of the embryonic *lateral splanchnic* series of arteries, which formed precociously, and persisted throughout subsequent development. Accessory vessels to the inferior pole of the kidney cross the ureter, and have been suggested as one cause of hydronephrosis, but this causal relationship cannot be regarded as proven. Very occasionally accessory renal arteries may arise from the coeliac or superior mesenteric arteries, near the bifurcation of the aorta or from the common iliac artery.

The fact of *renal vascular segmentation* was initially recognized by John Hunter in 1794, but the first detailed account of the primary branching pattern was provided by Graves (1954, 1956 *a* and *b*) who studied casts and radiographs of injected kidneys. He described five vascular segments: (1) *apical* occupying the medial side and anterior part of the superior pole; (2) *upper* (*anterior*) including the rest of the superior pole and the anterosuperior part of the central area; (3) the *lower* which encompasses the whole of the lower pole; (4) the *middle* (*anterior*) which lies between the upper (anterior) and lower segments; and (5) the *posterior* segment which includes the whole of the posterior aspect of the kidney between the apical and lower segments. Although Graves' terminology has been adopted internationally and used by some researchers in this field (Smith 1963; Sykes 1963, 1964), others have proposed more complex schemes including, for example, three posterior segments (Faller and Ungvary 1962); yet others have emphasized the great variability of the precise areas supplied by the segmental arteries (Fine and Keen 1966). Despite these somewhat divergent views, it is nevertheless important to emphasize that the vascular segments are supplied by arteries which have virtually no anastomoses with their neighbours and are thus end-arteries. In contrast, the larger *intrarenal veins* have no segmental organization, and anastomose freely.

Early this century (Brodel 1901) a relatively avascular longitudinal zone (the *'bloodless' line of Brodel*) was described as existing along the convex lateral border of the kidney, and this was proposed as the most suitable route for renal surgical incisions. However, it is now clear that many vessels cross this zone, which is far from 'bloodless', and that planned radial or intersegmental incisions are preferable.

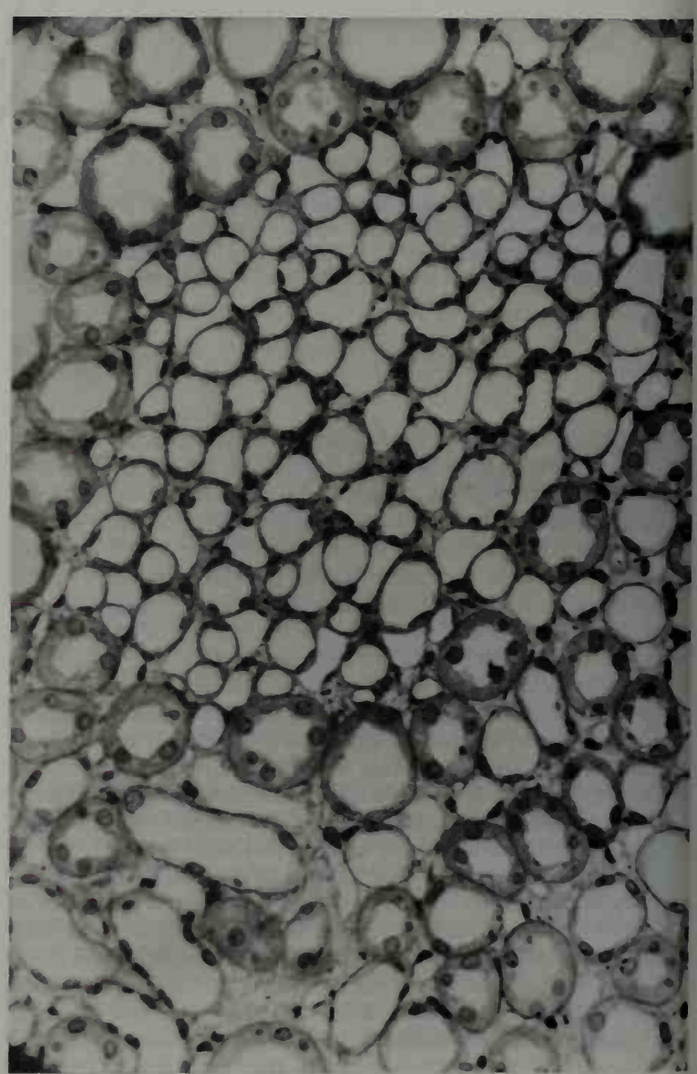


8.156B A diagram of the basic arrangements of the blood vessels in the mammalian kidney. Arteries—black outlines; capillaries—single black lines; veins—cross-hatched or full black. Note the variations in the pattern of the meshes in the capillary networks. See accompanying text for further description. (From *The Blood Vessels of the Kidney*, by Julia Fourman and D. B. Moffat, by courtesy of the authors and publishers, Blackwell Scientific Publications, Oxford, 1971.)

The initial branches of the segmental arteries provide the *lobar arteries*, usually one for each renal pyramid, which again divide just before entering the kidney substance into two or three *interlobar arteries*, extending towards the cortex on each side of the pyramid (i.e. between adjacent renal lobes). At the junction between the cortex and medulla, the interlobar arteries divide dichotomously into *arcuate arteries* which diverge at right angles from the parent stem. As they pursue their curved courses between cortex and medulla, each arcuate artery undergoes several further divisions, and from each of these branches a series of *interlobular arteries* ascend radially into the cortical substance. The terminations of adjacent arcuate arteries do not anastomose, but finally turn into the cortex as further interlobular arteries. Although the majority of the latter are branches of arcuate arterial branches, some also arise from the stem vessel and even from the terminal part of the interlobar arteries (**8**.156B).

The *interlobular arteries* may follow a simple course towards the superficial part of the cortex, or they may branch a few times *en route*, whilst some pursue a more tortuous course, recurving towards the medulla once or twice before again proceeding towards the renal surface. Some of the interlobular arteries pass straight through the surface of the kidney as *perforating arteries* (Hammersen and Staubesand 1961) to anastomose with the *capsular plexus* of vessels (which also receives *capsular branches* from the *inferior suprarenal*, *renal* and *testicular* or *ovarian* arteries).

The *afferent glomerular arterioles* are mainly side branches from the interlobular arteries, but a few arise directly from the arcuate and interlobar arteries. Those from the interlobular artery vary in their direction and angle of origin from the parent vessel—the deeper ones are directed obliquely back towards the medulla, the intermediate ones pass out horizontally from the parent stem, whilst the more superficial ones pass obliquely towards the renal surface before ending in a glomerulus (**8**.156A, B).



From the majority of the glomeruli (i.e. with the exception of the juxtamedullary ones, and a small proportion of those at intermediate levels in the cortex), the *efferent glomerular arterioles* soon divide to form a fine-meshed *peritubular capillary plexus*, which runs between and around the proximal and distal convoluted tubules. Thus, in the main renal cortical circulation there are *two* distinct sets of *capillaries* in series, glomerular followed by peritubular, the two being linked by the efferent glomerular arterioles. From the venous ends of the peritubular plexus, fine radicles converge to join *interlobular veins*, one of which accompanies each artery of the same name. Many of the interlobular veins commence immediately beneath the fibrous capsule of the kidney, by the convergence of a number of *stellate veins* which drain the most superficial parts of the renal cortex,

8.156C, D, E (opposite page) C A low-power, survey micrograph of a single nephric lobe following 'microfil' injection of the arterial tree of the human kidney. Note the clear distinction between cortex peripherally and the medulla converging on the renal papilla. The lobe is flanked by large interlobar arteries. Note also the arcuate arteries at the corticomedullary junction, the interlobular arteries ascending into the cortex, where the glomeruli are also visible, and the converging vascular bundles of the medulla. (Compare with 8.156B.)
D A higher magnification of the same preparation at the corticomedullary junction. Note juxtamedullary efferent arterioles, leaving the glomeruli, to form medullary vascular bundles (descending vasa recta).
E Transverse section through a vascular bundle (consisting of descending and ascending vasa recta). Surrounding the vascular bundle are sections of large collecting ducts, and thin and thick segments of the medullary loops (of Henle). (Preparations C–E kindly provided by Professor D. B. Moffat, Department of Anatomy, University College of Wales, Cardiff.)

and which are so named because of their appearance in surface view. During their course towards the corticomedullary junction, the interlobular veins also receive the terminations of some of the ascending vasa recta (*vide infra*), and then they end in the *arcuate veins* which accompany the arteries of the same name; but, unlike them, they anastomose with neighbouring veins to some extent. In turn, the arcuate veins drain into *interlobar veins* which by their convergence and anastomosis with neighbouring channels, ultimately form the renal vein.

The vascular supply of the *renal medulla* is derived in the main from the efferent arterioles of juxtamedullary glomeruli, but these are supplemented by efferent arterioles from more superficially placed glomeruli, and by a number of 'aglomerular' arterioles (probably the result of previous glomerular degeneration). The efferent arterioles destined for the medulla are relatively long, wide vessels, which contribute side branches to the neighbouring capillary plexuses before entering the medulla, and each then divides into twelve to twenty-five *descending vasa recta*. The latter, as their name suggests, pursue straight courses (to varying depths) in the renal medulla, and contribute side branches to a radially elongated capillary plexus (8.156A) which is closely applied to the descending and ascending limbs of Henle's loop and to the collecting ducts. The venous ends of the capillaries converge to *ascending vasa recta* which return to drain into the arcuate or interlobular veins. An essential structural feature of the vasa recta is that, particularly in the outer medulla, a considerable number of both ascending and descending vessels are grouped into *vascular bundles*. Within the latter the external aspects of the descending and ascending vasa recta are closely apposed to each other, whilst around the margins of the bundles, the vessels are closely applied to the limbs of the loop of Henle and to the collecting ducts. As the vascular bundles are traced centrally into the renal medulla, they come to contain fewer vessels, as some of their numbers terminate at successive levels in the neighbouring capillary plexuses. This close parallel apposition of descending and ascending vessels, with each other, and with the surrounding duct systems mentioned above, provides the structural basis for the countercurrent exchange and multiplier phenomena mentioned on a previous page, which characterize the physiological role of the renal medulla (p. 1395; 8.152D; 156D, E).

In terms of their *ultrastructure*, the renal vessels in their various regions show features that have been described elsewhere in this volume. The renal, interlobar and arcuate arteries are fairly typical 'large muscular arteries' (p. 625); the interlobular vessels are similar to 'small muscular arteries' in other organs, whilst the afferent glomerular vessels show a typical arteriolar structure with a muscular coat which is two to three cells thick. This and the connective tissue strata gradually diminish as the glomerulus is approached, until a point some 30–50 μm proximal to the glomerulus, where the arteriolar cells begin to show the modifications which characterize the *juxtaglomerular apparatus* (p. 1396). The efferent glomerular arterioles from the majority of the cortical glomeruli have slightly thicker walls and a narrower calibre than their corresponding afferent vessels. The peritubular

and medullary capillaries possess a well-defined pericapillary basal lamina, and their endothelial cells have a typically fenestrated cytoplasm (p. 628)—a structure also possessed by the ascending vasa recta, in contrast to the descending vasa, which have a thicker and continuous endothelium. The structure of the glomerular capillaries was considered above (p. 1399). Brief comments concerning the functional associations between the different parts of the nephric tubules and their associated blood vessels were given in the previous pages (p. 1395); for a much more detailed analysis consult Fourman and Moffat (1971).

Nerves of the kidney. The general sources of the nerves to the kidney are described on p. 1134). Nerve fibres passing directly from the plexuses around the arcuate arteries to innervate the juxtamedullary efferent arterioles and vasa recta have been described (Munkacsi and Newstead 1971). It is suggested that these might control blood flow between the cortex and medulla of the kidney, without affecting glomerular circulation.

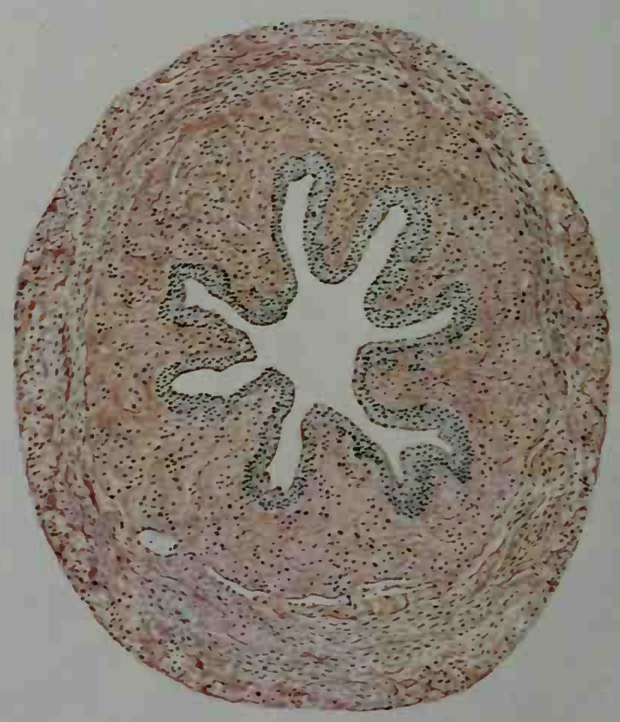
Lymph vessels of the kidney are described on p. 797.

Renal anomalies. The early pelvic position of the kidney (p. 213) may persist, and in these cases the organ usually derives its blood supply from the common iliac artery, and the hilum lies on its anterior aspect. Occasionally the kidneys may be connected by a transverse bar of renal tissue forming a 'horseshoe kidney'; generally the bar connects the lower poles of the kidneys and only rarely does it connect their upper poles. The ureters curve across the ventral aspect of the connecting bar of renal tissue, and may suffer partial obstruction at this level, with resultant hydronephrosis. Congenital absence or imperfect development of one kidney may occur, and may be compensated by enlargement of the kidney on the opposite side. Rarely the two kidneys may lie on the same side of the body. Single or multiple renal cysts of congenital origin are not uncommon; alternatively, widespread congenital polycystic disease may occur.

The Ureters

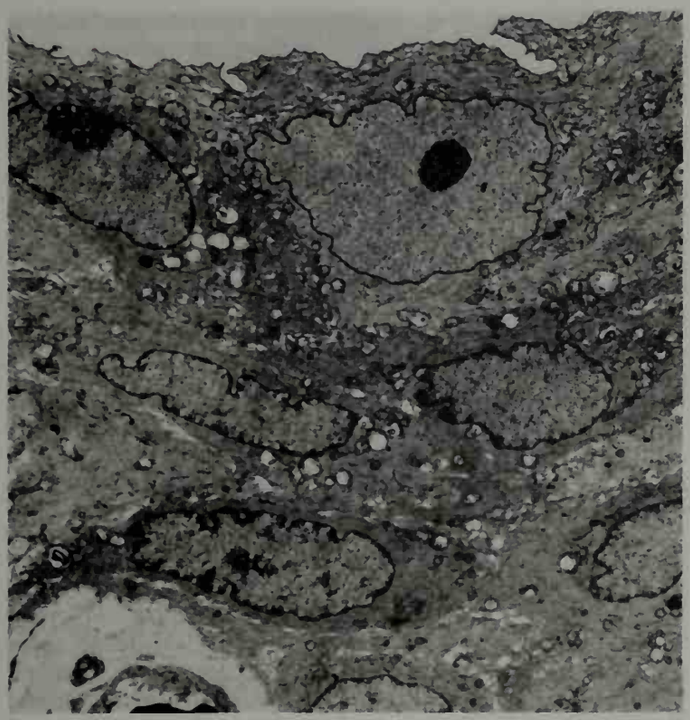
The ureters are the two muscular tubes whose peristaltic contractions convey the urine from the kidneys to the urinary bladder. Each measures from 25 to 30 cm in length, and is a thick-walled, narrow, cylindrical tube which is directly continuous superiorly with the funnel-shaped renal pelvis; a slight constriction may mark the site of transition (**8**.152A). It runs downwards and slightly medially in front of the psoas major, passes into the pelvic cavity, and opens into the base of the urinary bladder. Its position can be projected on the surface, where it is represented by a line from a point on the transpyloric plane 5 cm from the median plane, drawn almost vertically downwards, with a very slightly medial inclination, to the pubic tubercle. In general, its diameter is about 3 mm, but it is slightly constricted in three places: superiorly, at its junction with the renal pelvis; where it crosses the brim of the lesser pelvis at the medial border of the psoas major; and as it passes through the wall of the urinary bladder (this latter part being its narrowest portion).

The *pelvis of the kidney* has already been described (p. 1389).



The *abdominal part* of the ureter descends posterior to the peritoneum on the medial part of the psoas major, which intervenes between it and the tips of the transverse processes of the lumbar vertebrae (**8**.149). Anterior to the psoas major it crosses in front of the genitofemoral nerve and is itself obliquely crossed by the gonadal vessels. It enters the lesser pelvis by crossing anterior to either the end of the common, or the beginning of the external, iliac vessels.

At its origin the *right* ureter is usually overlapped by the descending part of the duodenum; in its descent it is lateral to the inferior vena cava, and is crossed anteriorly by the right colic and the ileocolic vessels, whilst near the superior aperture of the lesser pelvis it passes behind the lower part of the mesentery and the terminal part of the ileum. The *left ureter* is crossed by the left colic vessels and, near the superior aperture of the lesser pelvis, passes posterior to the sigmoid colon and its mesentery, lying in the posterior wall of the intersigmoid recess. At operation, because of these differences, the abdominal part of the left ureter is easier to expose than the right.



The *pelvic part* of the ureter is about the same length as the abdominal part; in both sexes it lies in the extraperitoneal areolar tissue. At first it descends posterolaterally on the lateral wall of the lesser pelvis, following the anterior border of the greater sciatic notch. Opposite the ischial spine it turns anteromedially to run in the fibrous adipose tissue above the levator ani to reach the base of the bladder. On the posterolateral pelvic wall it is anterior to the internal iliac artery and the commencement of its anterior trunk, dorsal to which are the internal iliac vein, lumbosacral nerve and sacro-iliac joint. Laterally it lies on the fascia covering the obturator internus and it progressively crosses and is medial to the umbilical artery, the obturator nerve, artery and vein, the inferior vesical artery and the middle rectal artery.

In the male, as it descends anteromedially, the ureter is crossed above and in front, and from lateral to medial, by the ductus deferens. Thereafter the ureter passes in front of, and slightly above, the upper end of the seminal vesicle and finally enters the bladder wall obliquely to open into the bladder at the lateral angle of the trigone (**8**.162). The terminal part of the ureter is surrounded by tributaries of the vesical veins.

In the female, the pelvic part of the ureter at first has the same general relations as in the male, though where it lies anterior to the internal iliac artery it is situated immediately behind the ovary and here forms the posterior boundary of the ovarian fossa (p. 1423). In its later forward and medial course to the bladder it has important relations to the uterine artery, the cervix of the uterus and the fornices of the vagina. It lies in the extraperitoneal connective tissue in the lower and medial part of the broad ligament of the uterus (parametrium; p. 1432); here it is intimately related to the uterine artery, which lies above and in front of the ureter for a distance of 2·5 cm and then crosses to gain the medial side of the ureter to ascend alongside the uterus. The ureter runs forwards slightly above the lateral fornix of the vagina and is here situated commonly about 2 cm lateral to the supravaginal portion of the cervix of the uterus (p. 1428), though this distance may vary from 1 to 4 cm. It then inclines medially to reach the bladder and in doing so it has a variable relation to the front of the vagina. As the uterus is commonly deviated to one side of the median plane, one ureter may be more extensively apposed to the front of the vagina than the other. In most cases the left ureter has the more extensive relation and it may cross the median plane; the reverse may occur and sometimes one ureter may not lie

8.158A A transverse section through the lower third of a human ureter. Note great thickness of muscular wall. Stained with haematoxylin and eosin. Magnification about × 30.

8.158B Transmission electron micrograph showing the transitional epithelium lining the ureter (rat). (Magnification × 4,000.) (Prepared and photographed by Mrs. Susan Smith, Department of Anatomy, Guy's Hospital Medical School, London.)

in front of the vagina, in which case a much longer part of the other ureter than usual lies in front of it.

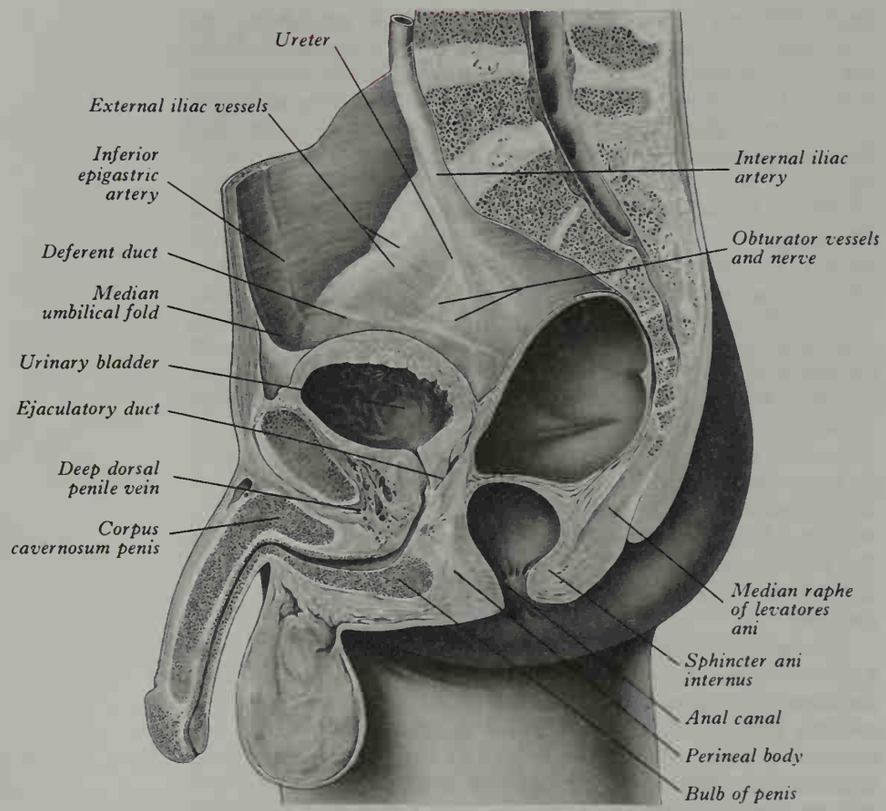
In the distended bladder, in both sexes, the ureteric openings are about 5 cm apart, this distance being reduced somewhat in the empty viscus. In its oblique course through the vesical wall, the ureter becomes compressed and hence flattened when the bladder is distended, and this may prevent regurgitation of urine from the bladder into the ureter, though peristalsis of the ureteric muscle is also a factor in this effect.

The ureter, the renal pelvis and the calices can be demonstrated in the living subject by radiographs taken (1) after the intravenous injection of a radio-opaque substance excreted in the urine (descending or *excretion pyelography*), or (2) after injection of similar solutions into the ureter by means of a ureteric catheter passed through an operating cystoscope (ascending or *retrograde pyelography*). The resulting radiographs are termed *pyelograms* (*see* e.g. **8**.149). The normal cupping of the minor calices by the projecting renal papillae is clinically important, because it may be obliterated by pathological conditions (such as hydronephrosis) which are associated with chronic distension of the ureter and renal pelvis consequent upon some source of urinary back-pressure.

URETERIC STRUCTURE

The ureter has three coats: fibrous, muscular and mucous.

The *fibrous coat* is continuous at one end with the fibrous capsule of the kidney in the floor of the renal sinus, while at the other it is lost on the wall of the bladder.



The *muscular coat* in the pelvis, calices and upper two-thirds of the ureter consists of two layers of non-striated myocytes, an inner longitudinal and an outer circular. The former begins at the attachment of the minor calices to the renal papillae. The circular muscle in this region becomes prominent and forms rings around the bases of the papillae; the periodic contractions of this muscle may have the effect of 'milking' the papillae and squeezing urine out of the ducts of Bellini. Subsequent observations in the main confirm this, but separated fasciculi of muscle fibres have been shown to extend into the caliceal wall. No pelvi-ureteric sphincter has been detected. Clear definition of circular and longitudinal strata of muscle fibres in the upper urinary tract was considered to be obscured by a plexiform arrangement of fibres (Gosling 1970). In the lower third of the ureter, an additional outer longitudinal muscular layer is added, and the inner longitudinal layer becomes less distinct. In its oblique passage through the wall of the bladder the muscle is arranged entirely in a longitudinal direction, and this, on contraction, has the effect of keeping patent this part of the ureter. The muscle of the ureter is not compactly arranged as in the intestine but is infiltrated by connective tissue derived from the mucosal and fibrous layers. Furthermore, as in the case of the urinary bladder, the muscular strata described above intermingle to such an extent that they cannot be separated into three clearly defined strata. Various accounts of the arrangement of muscle fasciculi at the ureterovesical junction have been recorded. The muscle fibres of the ureter are continued into the superficial strata of the trigone (p. 1406), but disagreement over details has not yet been resolved (Tanagho and Pugh 1963; Tanagho *et al.* 1968). The muscular coat of the ureter undergoes peristaltic contractions progressing downwards from the renal pelvis and calices. The muscular tone and peristaltic activity of the ureter are materially influenced by the rate of urine excretion by the kidney, both being increased if the renal output rises. With average renal output the ureter propels jets of urine into the bladder at the rate of four or five a minute.

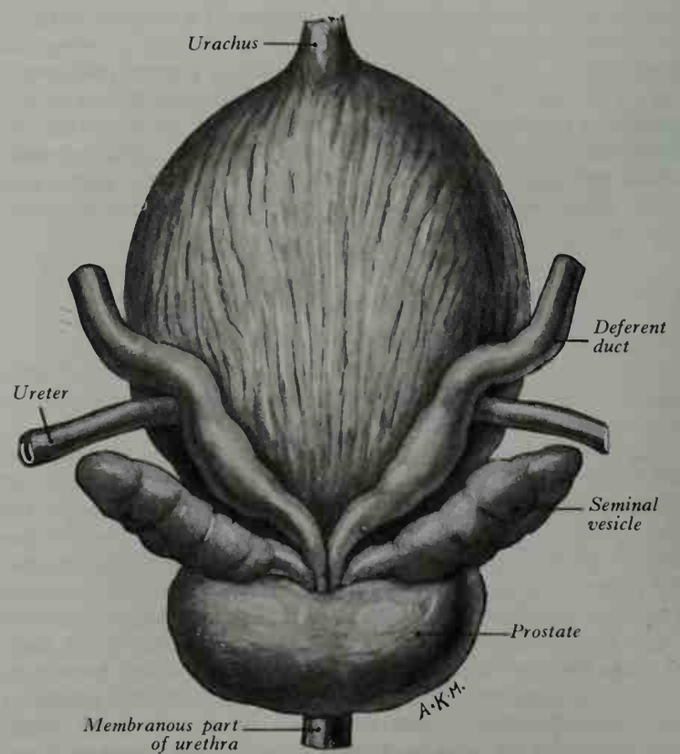
The *mucous coat* is smooth, and presents about six longitudinal folds which become effaced by distension. It is continuous with the mucous membrane of the bladder below, while it is prolonged over the papillae of the kidney above. It consists of fibrous tissue containing many elastic fibres, and covered with transitional epithelium (urothelium), four or five cells thick in the ureter and two or three cells thick in the pelvis and calices. No distinct submucosa is present. The mucous membrane at the entrance of the ureter into the bladder is slightly infolded but it is very doubtful whether this arrangement has any valvular action.

The *arteries* supplying the ureter (Daniel and Shackman 1952) are derived from the renal, abdominal aortic, testicular (or ovarian), common iliac, internal iliac, vesical and uterine vessels, the branches supplying the different parts of the ureter in its course and being subject to much variation. The longitudinal anastomosis between these branches on the wall of the ureter is good. In the treatment of certain clinical conditions affecting the urinary bladder, the lower part of the ureter may be divided, a short length mobilized and implanted into the wall of a neighbouring part of the colon. It has been shown that there is a danger of ischaemic necrosis of the lower part of the divided ureter if the anastomotic vessels in this region are only minute, and that the ureter may be more safely divided 2 cm below the bifurcation of the common iliac artery. The branches from the inferior vesical artery (p. 720) are constant in their occurrence and supply the lower part of the ureter as well as a large part of the trigone of the bladder.

The *lymph vessels* of the ureter are described on p. 797.

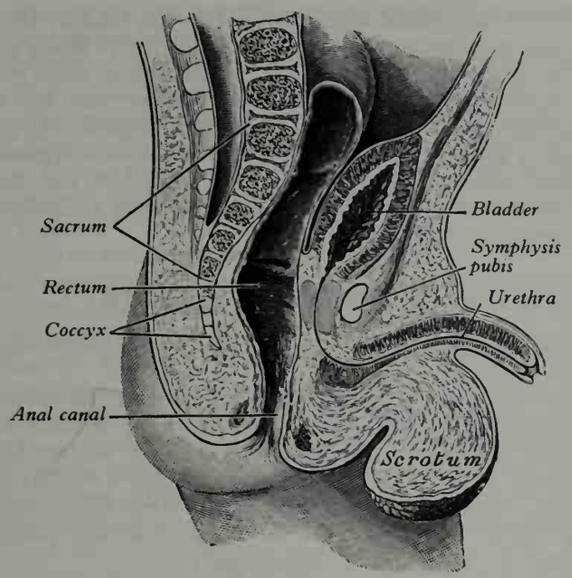
The *uretic nerves* (p. 1134; **7**.230) are derived from the renal, aortic, and superior and inferior hypogastric plexuses; through these plexuses fibres are derived from the lower three thoracic and first lumbar and the second to the fourth sacral segments of the spinal cord. Small ganglia and isolated ganglion cells have been reported in the fibrous and muscular coats. They are most numerous in the lower part of the ureter and relatively sparse elsewhere. The ureteric plexuses contain both sympathetic and parasympathetic fibres, but their function is not clear, and it has been maintained that they are largely sensory in nature, since they can be stripped off the ureter without affecting its muscular activities. In rodents (Dixon and Gosling 1971) a combination of ultrastructural observations with the histochemical localization of adrenergic and cholinergic nerve fibres has indicated some regional differences, the former type predominating in the major calices and pelvis of the ureter. Ganglion cells have not been observed in the wall of the superior region of the ureter. Schulman (1975) has studied the development, pre- and perinatal, of the ureteric nerves in mammals (rabbit) by histochemical demonstration of adrenergic and cholinergic fibres. The latter appear earlier and the former are poorly developed even at birth, a finding which, on phylogenetic grounds, is considered to support the views of Cauna *et al.* (1969), Gosling and Dixon (1974), and others that the cholinergic fibres are afferent.

8.159 A median sagittal section to show male internal and external genitalia, etc. A number of structures (e.g. obturator vessels, ureter) are only faintly visible through the overlying peritoneum.



Ultrastructural studies (Notley 1969, 1971) of the intrinsic nerves of the ureter largely confirm the findings of light microscopy. Non-myelinated nerve fibres lie in close proximity to muscle fibres of vessels and the ureteric wall, but no specialized motor endings have been observed. No ganglion cells were noted.

Applied Anatomy. As in the case of the gut (p. 1333), excessive ureteric distension or spasm of its muscle is an adequate stimulus to provoke severe pain (renal colic). This may be produced, for example, by a stone (calculus) causing incomplete and intermittent obstruction in the ureter, particularly if the stone is gradually forced down the ureter by the muscle spasm. The pain, which is spasmodic and agonizing, is referred to cutaneous areas innervated from the same segments of the spinal cord as supply the ureter, mainly T. 11–L. 2 (p. 1138). It commences in the loin and shoots downwards and forwards to the groin and the scrotum or labium majus; it may extend into the upper part of the front of the thigh by radiation along the genitofemoral nerve (L. 1, 2), and the cremaster (innervated by this nerve) may undergo reflex contraction and retract the testis. A ureteric stone is liable to become impacted at one of the constricted parts of the ureter, namely, its cranial end, where it crosses the brim of the lesser pelvis, or as it passes through the bladder wall; radiologically, such an impacted stone would be seen respectively near the tip of the transverse process of the second lumbar vertebra, or overlying the sacro-iliac joint, or slightly medial to the ischial spine. Sometimes the ureter is duplicated on one or both sides and the two tubes may remain distinct as far as the bladder; they rarely open separately into the bladder in such cases.



The Urinary Bladder

The urinary bladder (**8**.159), solely a reservoir, varies in its size, shape, position and relations according to the amount of fluid that it contains, as well as with the state of distension of neighbouring viscera. When empty it is entirely within the lesser pelvis, but as it becomes distended it expands upwards and forwards into the abdominal cavity.

The empty bladder is somewhat like a tetrahedron and has a base, neck, apex, superior surface and two inferolateral surfaces. The *fundus* or *base* is triangular and directed backwards and downwards. In the female (**8**.183) it is closely related to the anterior wall of the vagina. In the male it is related to the rectum, but its upper part is separated from the rectum by the rectovesical pouch of peritoneum, and below that the seminal vesicles and deferent ducts separate the two viscera (**8**.160). In the triangular interval between the two deferent ducts, the bladder and the rectum are separated only by the rectovesical fascia (p. 1421); the inferior part of this triangular interval may often be obliterated by the approximation of the deferent ducts above the prostate. Although the fundus (or base) of the bladder should be, by definition, the lowest region of the bladder, it is the *neck* which is in fact the lowest and also the most fixed part of the bladder; it lies 3 to 4 cm behind the lower part of the symphysis pubis (i.e. a little above the plane of the inferior aperture of the lesser pelvis). It is pierced by the internal urethral orifice and is subject to but little alteration in position with varying conditions of the bladder and rectum. There is no special constriction of the bladder at the site of the neck. In the male the neck rests on, and its wall is in direct continuity with, the base of the prostate; in the female it is related to the pelvic fascia which surrounds the upper part of the urethra. The *apex* in both sexes is directed forwards towards the upper part of the symphysis pubis, and from it the median umbilical ligament (urachus, p. 1405) is continued upwards on the posterior surface of the anterior abdominal wall to the umbilicus; the peritoneum folded over this ligament is the median umbilical fold. The *superior surface*, triangular in shape, is bounded on each side by a lateral border that runs from the apex to the entrance of the ureter into the bladder, and by a posterior border which corresponds with a line joining the entrances of the ureters into the bladder. In the male the superior surface is completely covered with peritoneum, which extends slightly on to the base and is continued behind into the rectovesical pouch, at the sides into the paravesical fossae, and at the front into the median umbilical fold. It is in contact with the sigmoid colon and the terminal coils of the small intestine. In the female the superior surface is almost entirely covered with peritoneum, but near its posterior border the peritoneum is reflected from it to the uterus at the level of the internal os (i.e. the junction of the body and cervix of the uterus), forming the vesico-uterine pouch. The

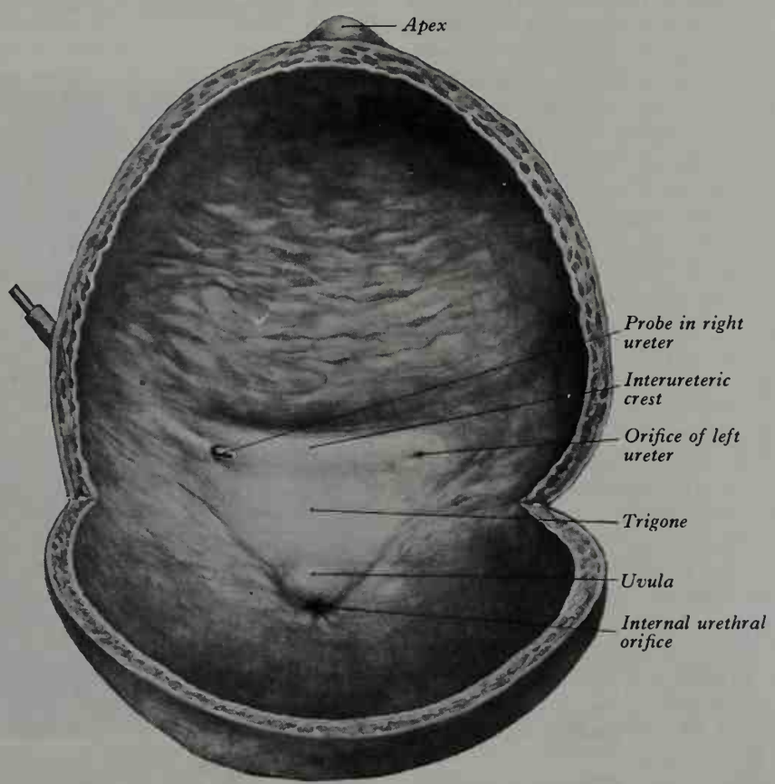
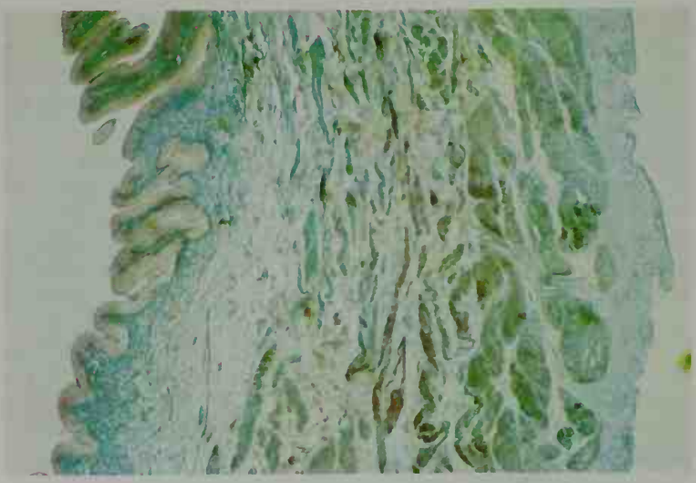
8.161 A sagittal section of the pelvis of a newborn male infant. Note the abdominal position of the urinary bladder.



posterior part of the superior surface, devoid of peritoneum, is separated from the supravaginal part of the uterine cervix by fibro-areolar tissue. Each *inferolateral surface* in the male is separated anteriorly from the pubis and puboprostatic ligaments by an adipose mass termed the retropubic pad; further posteriorly it is separated by fascia from the levator ani and obturator internus. In the female the relations are the same, except that the puboprostatic are replaced by the pubovesical ligaments. The inferolateral surfaces are not covered by peritoneum.

As the bladder fills, its borders become rounded off and it assumes an ovoid form. In front it displaces the parietal peritoneum on the suprapubic region of the abdominal wall, so that the inferolateral surfaces (now becoming the anterior surface of the distended bladder) rest against the anterior abdominal wall without the intervention of peritoneum for some distance above the symphysis pubis; this distance varies with the degree of distension of the bladder, but commonly, when the bladder is distended to an average degree, it measures about 5 cm, though in excessive distension it may extend as far as the umbilicus or even higher. Thus the full bladder may be approached surgically by incisions or punctures through the anterior abdominal wall a little above the symphysis pubis without traversing the peritoneum. The summit of the full bladder is directed upwards and forwards above the point of attachment of the median umbilical ligament, so that the peritoneum, which follows the ligament, forms a supravesical recess of varying depth between the summit and the anterior abdominal wall; the recess often contains coils of small intestine.



At birth (**8**.161), the bladder lies at a relatively higher level than in the adult; the internal urethral orifice is at the level of the *upper* border of the symphysis pubis and the bladder is an abdominal, rather than a pelvic organ, extending about two-thirds of the distance up to the umbilicus. It progressively descends until it reaches its adult position shortly after puberty.

THE VESICAL LIGAMENTS

Each side of the bladder is connected to the tendinous arch of the pelvic fascia (p. 561) by a condensation of fibro-areolar tissue, termed the *lateral true ligament* of the bladder. Anteriorly the same tissue forms two thickened bands, on each side of the median plane, termed the lateral and medial puboprostatic ligaments in the male. The *lateral puboprostatic ligament* extends from the anterior end of the tendinous arch of the pelvic fascia downwards and medially to blend with the upper part of the sheath of the prostate; the *medial puboprostatic ligament* is attached to the back of the pubic bone near the middle of the symphysis and passes downwards and backwards to the sheath of the prostate, forming the floor of the retropubic space. In the female similar bands are termed *pubovesical ligaments*. The *apex* of the bladder is joined to the umbilicus by the remains of the urachus, which forms the *median umbilical ligament*. The lumen of the lower part of the urachus persists throughout life and is lined by modified, transitional epithelium. It may communicate with the cavity of the bladder (Begg 1930). As the veins of the vesical venous plexus stream backwards from the lateral borders of the base of the bladder to join the internal iliac veins, they are enveloped on each side in a band of fibro-areolar tissue which is sometimes termed

8.162 Anterior aspect of the interior of the urinary bladder.

The section shows the folded transitional epithelium (grey-brown on the left), the connective tissue (deep green), and fasciculi of the detrusor muscle (green-brown, to the right), surrounded externally by the connective tissue adventitia. × 20.

the *posterior ligament* of the bladder. The functional role of the various vesical 'ligaments' is *presumed* to be supportive.

From the superior surface of the bladder the peritoneum is carried off in a series of folds which are termed the 'false' ligaments of the bladder, on the dubious distinction that they do not share the supportive function imputed to the (true) 'ligaments' noted above. Anteriorly there are three folds: the *median umbilical fold* over the median umbilical ligament, and two *medial umbilical folds* over the obliterated umbilical arteries (**8.**94). The reflexions of the peritoneum from the bladder to the side walls of the pelvis form the *lateral false ligaments* while the sacrogenital folds (p. 1324) constitute the *posterior false ligaments*.

THE VESICAL INTERIOR

The mucous membrane of the bladder (**8.**163) is, over the greater part of the viscus, only loosely attached to the subjacent muscular layer and develops folds when the bladder is contracted: the folds are effaced when the bladder is distended. Over a small triangular area, the *trigone of the bladder*, immediately above and behind the internal orifice of the urethra, the mucous membrane is firmly bound to the muscle layer, and is always smooth. The antero-inferior angle of the trigone is formed by the internal orifice of the urethra, its posterolateral angles by the orifices of the ureters. The superior boundary of the trigone is a slightly curved ridge, termed the *interureteric crest*, which connects the two ureteric orifices and is produced by the continuation into the bladder wall of the inner longitudinal coats of the ureters. (For details of the musculature of the trigonal region, consult Uhlenhuth *et al.* 1952; Woodburne 1965, 1968.) The lateral parts of this ridge extend beyond the openings of the ureters; they are named the *ureteric folds* and are produced by the terminal portions of the ureters as they run obliquely through the bladder wall. When the living bladder is examined with a cystoscope the interureteric crest appears as a pale band, and forms an important guide to the ureteric orifice in guiding a ureteric catheter into it.

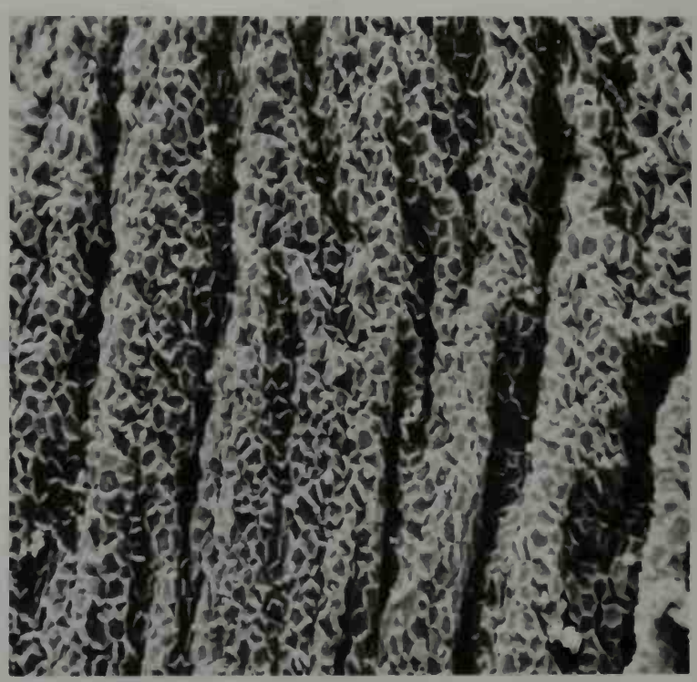
The *orifices of the ureters*, placed at the posterolateral angles of the trigone, are usually slit-like in form. In the contracted bladder they are about 2·5 cm apart and about the same distance from the internal urethral orifice; in the distended bladder these measurements may be increased to about 5 cm.

The *internal urethral orifice* is placed at the apex of the trigone, in the most dependent part of the bladder, and is usually somewhat crescentic in section; in adult males, particularly those past middle age, the mucous membrane immediately behind it exhibits a slight elevation, caused by the median lobe of the prostate and termed the *uvula* of the bladder.

The mean capacity of the living urinary bladder in the male adult is 220 ml, varying from 120 to 320 ml (Thompson 1919). Micturition commonly takes place when the bladder contains about 280 ml of urine. Filling of the bladder up to about 500 ml may be tolerated, but at levels much above this, pain is experienced due to the tension in the bladder wall, and reflex contractions then begin to make micturition urgent. The pain is referred to the cutaneous areas supplied by the same segments of the spinal cord as supply the bladder (T. 11–L. 2; S. 2–4), namely the lower part of the anterior abdominal wall, the perineum and, in the male, the penis.

VESICAL STRUCTURE OF THE BLADDER

The bladder has a three-layered wall—serous, muscular and mucous (**8.**163A).



The *serous*, peritoneal covering has been described above.

The *muscular* stratum, which constitutes the *detrusor muscle*, consists of three layers of nonstriated myocyte: an external and an internal of longitudinal fibres, and a middle of circular fibres. As in the case of the ureter (p. 1403), there is much intermingling of the muscle fibres in these layers, so that they cannot be separated into three clearly defined strata.

The fibres of the *external longitudinal layer* pass in a more or less longitudinal manner, along the inferolateral surfaces of the bladder, over its apex on to the superior surface, and then descend over the base to blend with the capsule of the prostate or with the anterior region of the vagina. Some of the longitudinal fibres are carried on to the front of the rectum, and are named the *rectovesical muscle*. Others traverse the medial puboprostatic ligaments and are attached to the lower part of the pelvic surface of the pubis on each side. They are termed the *pubovesical muscles*. (It is the presence of these muscular components in the ligaments of the bladder which is the chief evidence of their supportive role.) At the sides of the bladder the fibres are arranged obliquely and intersect one another.

The fibres of the *middle, circular, layer* are very thinly and irregularly scattered on the body of the organ, and, although to some extent placed transverse to its long axis, are for the most part arranged obliquely. Towards the cervical part of the bladder they are disposed in a circular layer, forming the *sphincter vesicae*, which surrounds the internal urethral orifice. Many authorities state that no completely sphincteric fascicles occur; some of these strands are continuous with prostatic muscle fibres which encircle the proximal part of the urethra in the male.

The *internal longitudinal layer* is thin, and its fasciculi have a

reticular arrangement, but with a tendency to assume for the most part a longitudinal direction.

Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the dorsum of the prostate, and are inserted by means of a fibrous process into the median lobe of the organ. They are the *muscles of the ureters*, described long ago (Bell 1812) as serving to maintain the oblique direction of the ureters, and so prevent the reflux of the urine into them during contraction of the bladder.

There is no muscularis mucosae in the bladder wall.

The *sphincter vesicae* (internal sphincter), composed of nonstriated muscle, and the *sphincter urethrae* (external sphincter), composed of striated muscle, both control the outflow from the bladder; it is usually considered that they can function independently, and the sphincter vesicae prevents urine leaking into the prostatic urethra, where its presence would arouse a desire to micturate. (*See*, however, further discussion on p. 1409.)

The *mucous membrane* is pale pink in colour; it is continuous above with that of the ureters, and below with that of the urethra; the epithelium covering it is of the transitional variety. The loose texture of the lamina propria allows the mucosa to be thrown into folds or *rugae* when the bladder is empty. Over the trigone it is closely attached to the muscular coat, and is not thrown into folds, but is smooth and flat. There are no true glands in the mucous membrane of the bladder, though certain mucous follicles, which exist especially near the neck of the bladder, have been regarded as such. Some believe that there are true mucous glands near the internal urethral orifice, both in the bladder (*subtrigonal glands*) and the prostatic urethra (*subcervical glands*), and maintain that enlargement of these may obstruct the outflow of urine from the bladder. The transitional epithelium of the ureter and bladder contains alkaline phosphatase, though the significance of this is not clear. Transplantation of pieces of bladder epithelium into the sheath of the rectus abdominis induces the formation of bone in that site (Huggins 1931), but it is suggested (Johnson and McMinn 1956) that, apart from alkaline phosphatase, other factors may be involved in the induction of this heterotopic bone formation. Ectopic ossification in sites containing potentially osteogenic cells is a well-known phenomenon, of which this is merely an instance.

8.164 The whole length of the lumen of the male urethra exposed by an incision extending into it from its dorsal aspect. Note openings of prostatic utricle and ejaculatory ducts on the colliculus seminalis.

Vessels and Nerves

The principal *arteries* of supply to the bladder are the superior and inferior vesical, derived from the anterior trunk of the internal iliac artery. The obturator and inferior gluteal arteries also send small branches to it, and in the female additional branches are derived from the uterine and vaginal arteries.

The *veins* form a complicated plexus on the inferolateral surfaces near the prostate, and pass backwards in the posterior ligaments of the bladder to end in the internal iliac veins.

The *lymph vessels* are described on p. 797.

The *nerves* supplying the bladder form the vesical plexus (*see* pp. 1135, 1137) and consist of both sympathetic and parasympathetic components, each of which contains motor (efferent) and sensory (afferent) fibres. The efferent parasympathetic fibres, arising from the second to the fourth sacral segments of the spinal cord (nervi erigentes), convey motor fibres to the detrusor muscle and inhibitory fibres to the sphincter vesicae; if they are destroyed normal micturition is not possible. The sympathetic efferent fibres from the lower two thoracic and upper two lumbar segments of the spinal cord are said to supply inhibitory fibres to the detrusor and motor fibres to the sphincter vesicae, though it is claimed that they are mainly vasomotor in function and that normal filling and emptying of the bladder are controlled exclusively by the parasympathetic nervous system. The sphincter urethrae (external sphincter), a somatic striated muscle, is also concerned in controlling micturition and is supplied by the pudendal nerve (S. 2–4). As regards the sensory innervation of the bladder, there are fibres concerned with pain and those concerned with conscious awareness of bladder distension. The pain fibres, which are stimulated by distension or by spasm of the bladder wall, or by a stone or inflammation or malignant disease irritating the bladder, run in both the sympathetic and parasympathetic nerves, the latter pathway being predominant. Because of this double pathway of the pain fibres, simple division of the appropriate sympathetic path (e.g. 'presacral neurectomy') or division of the superior hypogastric plexus (p. 1135) does not materially relieve bladder pain. In the spinal cord the pain fibres lie in the anterolateral white columns, and bladder pain may be considerably relieved by cutting these tracts (bilateral anterolateral cordotomy). On the other hand, the nerve fibres subserving awareness of fullness of the bladder run in the posterior columns of the spinal cord (fasciculus gracilis), so that after anterolateral cordotomy for the relief of pain, the patient is still aware of bladder fullness and of the desire to micturate.

Applied Anatomy. The distended bladder may be ruptured by injuries of the lower half of the anterior abdominal wall or by fracture of the pelvis; the rupture may be extraperitoneal or, if involving the superior surface of the bladder, it is usually complicated by tearing of the peritoneum and consequent escape of vesical contents into the peritoneal cavity. If there is progressive chronic obstruction to the outflow of urine from the bladder, e.g. by enlargement of the prostate (p. 1143) or by stricture of the urethra, the bladder becomes distended and its musculature hypertrophies, its fasciculi increasing in size and interlacing in all directions, giving rise to what is known as 'the trabeculated bladder'. The mucous membrane between these bundles forms 'diverticula' of the bladder which may contain phosphatic concretions. When the bladder outflow is thus obstructed, it is not able to empty itself completely and after micturition some urine is retained and may become infected; the infection may extend along the ureters to the kidneys. Back pressure from the bladder thus distended may cause gradual dilatation of the ureter and its pelvis, and of the renal collecting tubules. Lesions of the fasciculus gracilis in the spinal cord (e.g. tabes dorsalis) cause loss of appreciation of bladder distension and of the desire to micturate; the bladder distends and may empty

merely by overflow. In severe lesions of the spinal cord above its sacral segments, the efferent and afferent nerve tracts involved in normal micturition may be interrupted, resulting in 'automatic' emptying of the bladder.

The vesical interior can be examined with the cystoscope, introduced along the urethra after distending the bladder with fluid. A special cystoscope can be used to catheterize the ureter, for the purpose of obtaining a specimen of urine from either kidney, or in order to inject radio-opaque fluid into ureter and renal pelvis for retrograde pyelography (**8**.149). The outline of the bladder can also be demonstrated when filled with the same fluid.

Puncture of the distended bladder may be performed just above the symphysis pubis without injuring the peritoneum (*suprapubic cystostomy*). When the bladder contains about 300 ml of fluid, its antero-inferior surface is in contact with the anterior abdominal wall, without the interposition of peritoneum, for about 7·5 cm above the pubic crest. Access to the bladder, for the purpose of removing calculi, is almost always effected by this suprapubic route. In the female, owing to the shortness of the urethra and its ready dilatability, calculi and foreign bodies and new growths, when of small size, may be removed by the urethral route. Congenital abnormalities of the bladder are described on p. 221.

The Male Urethra

The male urethra (**8**.159, 164), from 18 to 20 cm long, extends from an internal orifice in the urinary bladder to an external opening, or meatus, at the end of the penis. It may be considered in three regional parts: *prostatic*, *membranous* and *spongiose*, and presents a double curve in the ordinary flaccid state of the penis (**8**.159). Except during the passage of fluid along it, the urethral canal is a mere slit; in the prostatic part the slit is transversely arched; in the membranous portion, stellate; in the spongiose portion, transverse; while at the external orifice it is sagittal.

The prostatic part, which is the widest and most dilatable part of the urethra, is about 3 cm long, and runs almost vertically through the prostate from its base to its apex, but with some angulation between its supra- and infra-collicular sections (Glenister 1962). It lies nearer the anterior than the posterior surface of the prostate. It is widest in the middle and narrowest below, adjoining the membranous part; on section it is crescentic, convex ventrally.

Its shape on section is due to the presence on the posterior wall (or floor) of a narrow median longitudinal ridge formed by an elevation of the mucous membrane and its subjacent tissue, termed the *urethral crest* (**8**.164). On each side of the crest there is a shallow depression, termed the *prostatic sinus*, the floor of which is perforated by the *orifices of the prostatic ducts*. About the middle of the length of the urethral crest the *colliculus seminalis* forms an elevation on which the slit-like orifice of the prostatic utricle is situated; on each side of, or just within, this orifice there is the small opening of the ejaculatory duct. The *prostatic utricle* is a cul-de-sac about 6 mm long, which runs upwards and backwards in the substance of the prostate behind the median lobe. Its walls are composed of fibrous tissue, muscular fibres, and mucous membrane; the latter presents the openings of numerous small glands. It is developed from the paramesonephric ducts or urogenital sinus, and is thought to be homologous with the vagina of the female (p. 221). The prostatic utricle is therefore called by some 'the *vagina masculina*', but the more usual view is that it is a uterine homologue, and hence the term 'utricle'. The ejaculatory ducts are described on p. 1417.

The membranous part is the shortest, least dilatable, and, with the exception of the external orifice, the narrowest section of the urethra. It descends with a slight ventral concavity from the prostate to the bulb of the penis (**8**.159), passing through the perineal membrane about 2·5 cm postero-inferior to the pubic symphysis. The hinder part of the bulb of the penis is closely apposed to the inferior aspect of the urogenital diaphragm (perineal membrane), but, anteriorly, it is slightly separated from the latter, so that the wall of the urethra is related anteriorly neither to the perineal membrane nor the penile bulb. If this part of the anterior wall of the urethra is regarded as 'membranous', it measures about 2 cm, whilst the length of this part of the urethra is posteriorly only 1·25 cm.

The membranous urethra is surrounded by the fibres of the sphincter urethrae (p. 563). In front of it, the deep dorsal vein of the penis enters the pelvis between the transverse perineal ligament and the arcuate ligament of the pubis; one bulbo-urethral gland is sited on each side of this part of the urethra.

The spongiose part is contained in the corpus spongiosum penis (p. 1419). It is about 15 cm long, and extends from the end of the membranous urethra to the external urethral orifice on the glans penis. Commencing below the perineal membrane, it continues the ventrally concave curve of the membranous urethra to a point anterior to the lowest level of the symphysis pubis. From here, when the penis is flaccid, it curves downwards in the 'free' part of the penis. It is narrow, with a uniform diameter of about 6 mm in the penis; it is dilated at its commencement as the *intrabulbar fossa*, and again within the glans penis, where it becomes the *navicular fossa*. The enlargement of the intrabulbar fossa affects the floor and side walls but not the roof of the urethra. The bulbo-urethral glands open into the spongiose section of the urethra about 2·5 cm below the perineal membrane.

The *external urethral orifice* is the narrowest part of the urethra: it is a sagittal slit, about 6 mm long, bounded on each side by a small labium.

The epithelium of the urethra, except in its most anterior part, presents the orifices of numerous small mucous glands and follicles situated in the submucous tissue, and named the *urethral glands*. Besides these there are a number of small pit-like recesses, or *lacunae*, of varying sizes; the orifices of these are directed forwards, and may intercept the point of a catheter in its passage along the canal. One, larger than the rest, the *lacuna magna*, is situated on the roof of the navicular fossa.

Urethral Sphincters

Two sphincters surround the urethra. The internal *sphincter vesicae* (p. 1407) controls the neck of the bladder and the prostatic urethra above the opening of the ejaculatory ducts. It is composed of nonstriated muscle, is not under voluntary control, and is supplied by sympathetic and parasympathetic fibres derived from the vesical plexus (*vide supra* and also, p. 1135). The external sphincter, or *sphincter urethrae* (p. 563), closely surrounds the membranous urethra and consists of striated muscle; it is supplied by the perineal branch of the pudendal nerve (S. 2, 3 and 4) and is under voluntary control after early infancy.

The existence of a definable internal sphincter at the vesical exit, however, cannot be stated dogmatically, for there is much difference of opinion in regard to this. Many observers state that the nonstriated muscle fibres of the vesical neck are arranged in many directions, as in the wall of the bladder, and that no true band of circumferential fibres can be identified (for a short critical review, *see* Woodburne 1961; Angell 1969). However, all authorities appear to agree that a substantial aggregation of muscle tissue, with a considerable admixture of elastic and collagenous fibres, does exist at the vesical outlet (Vincent 1966*a*). The significance of this in the mechanisms of micturition is briefly described on p. 1409.

Male Urethral Structure

The urethra is composed of a mucous membrane, supported by submucous tissue which connects with the various structures through which it passes, and surrounded by muscle.

The *mucous membrane* of the urethra is continuous internally with that of the bladder, and externally with the skin covering the glans penis; it is prolonged into the ducts of the urethral, bulbo-urethral and prostatic glands, and into the deferent ducts and seminal vesicles, through the ejaculatory ducts. (This continuity is an important consideration in the spread of urethral infections.) In the spongiose and membranous urethral regions it is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it near the external urethral orifice; its epithelial lining is of the transitional variety as far as the orifice of the ejaculatory duct; thereafter it is composed of patches of pseudostratified columnar and stratified epithelium, amongst

which are situated diverticula of various sizes, some extending into the lamina propria as mucous glands (of Littré). Concretions similar to those found in the prostate may occur in these glands in old age. Near the external urethral orifice, the epithelium is stratified squamous in type.

The *submucous tissue* consists of a vascular erectile layer; outside this there is a layer of nonstriated myocytes, arranged into an inner longitudinal and an outer circular layer and best marked in the prostatic and membranous sections of the urethra.

The Female Urethra

The female urethra is about 4 cm long and 6 mm in diameter. It begins at the internal urethral orifice of the bladder, approximately opposite the middle of the symphysis pubis, and runs antero-inferiorly behind the symphysis pubis, embedded in the anterior wall of the vagina. It traverses the perineal membrane and ends at the external urethral orifice, an anteroposterior slit with rather prominent margins, which is situated directly anterior to the opening of the vagina and about 2·5 cm behind the glans clitoridis. Except during the passage of urine the anterior and posterior walls of the urethra are in apposition, and the epithelium is thrown into longitudinal folds, one of which, on the posterior wall of the canal, is termed the *urethral crest*. Many small mucous *urethral glands* and minute pit-like recesses or *lacunae* open into the urethra. On each side, near the lower end of the urethra, a number are grouped together and open into a duct, named the *para-urethral duct*; each duct runs down in the submucous tissue and ends in a small aperture on the lateral margin of the external urethral orifice. The urethral glands are considered to be the homologue of the male prostate, and the term '*female prostate*' is sometimes applied, but only to the glands of the proximal urethra. The glands, however, do not resemble male prostatic glandular tissue microscopically. Developmentally, the female urethra corresponds to the part of the prostatic urethra in the male that lies proximal to the opening of the prostatic utricle.

Female Urethral Structure

The female urethra contains muscular, erectile and mucous layers in its wall, as in the male.

The *muscular layer* is continuous with that of the bladder; it extends the whole length of the tube, and consists of internal longitudinal and external circular fibres. At the vesical end of the urethra, the circular muscle of the bladder is thickened and forms the sphincter vesicae (internal sphincter). In addition to this, just above the perineal membrane, the female urethra is surrounded by the sphincter urethrae, as in the male. The nerve supply of these two sphincters is the same as that in the male (pp. 563, 1135, 1407).

A thin layer of *spongiose erectile tissue*, containing a plexus of large veins, intermixed with bundles of nonstriated muscle fibres and connective tissue rich in elastin fibres, lies immediately beneath the mucous coat.

The *mucous membrane* is pale; it is continuous externally with that of the vulva, and internally with that of the bladder. Near the bladder it consists of transitional epithelium, grading more distally into non-keratinizing stratified squamous epithelium interspersed with pseudostratified columnar epithelium, and small mucous recesses and glands. Its external orifice is surrounded by a few mucous follicles.

The female urethra is much more readily dilatable than that of the male, and the passage of catheters or cystoscopes is a much easier process.

MICTURITION

Accumulation of urine in the bladder is accompanied by modification of tone of the detrusor muscle, so that the intravesical tension does not rise greatly until a considerable filling of the bladder has occurred. When the tension in the bladder rises, sensory nerves are stimulated, the desire to micturate is felt and, if neglected, a sensation of fullness of the bladder and finally pain supervenes. These sensations are accompanied by rhythmic reflex contractions of the detrusor muscle. Until micturition starts, voluntary restraint is exercised by coincident inhibition of the detrusor and contraction of the sphincter urethrae and the perineal muscles (Denny-Brown and Robertson 1933). There is no evidence that the sphincter vesicae is under voluntary control, but a reciprocal increase in tone of this muscle accompanies relaxation of the detrusor. The first stage of the act of micturition is a relaxation of the perineal muscles, except the sphincter urethrae, and a contraction of the muscles of the abdominal wall. This is followed by firm contraction of the detrusor and relaxation of the sphincter vesicae. The flow of urine begins on subsequent relaxation of the sphincter urethrae, the bladder being then emptied by the contraction of the detrusor assisted by the action of the muscles of the abdominal wall which raise the intra-abdominal pressure. As the act is completed, the bladder muscle relaxes and the sphincter vesicae contracts. Finally the sphincter urethrae is closed and, in the male, the last drops of urine are expelled from the bulbar portion of the urethra by the action of the bulbospongiosus.

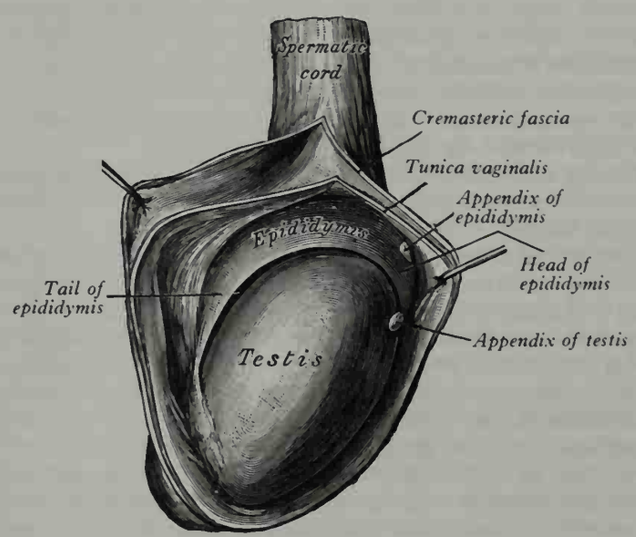
This straightforward account of the supposed behaviour of the various muscular forces involved in micturition represents widely held views, but does not take into account certain dissensions and modifications. Much of the controversy centres around the role of the so-called *sphincter vesicae* (*vide supra*), most observers being in agreement on the efficacy of the external sphincter, the voluntarily controlled, striated, *sphincter urethrae*. An interesting theory, supported by considerable experimental evidence (Vincent 1966), suggests that when the pelvic floor is relaxed, the aggregation of nonstriated muscle at the bladder neck, even if contracted, cannot completely oppose the detrusor muscle. Conversely, the upward pressure of the pelvic floor, when it returns to normal tonus, moulds the bladder neck tissues into an efficient plug to the outlet. This theory receives support from observations on the intraluminal pressure in the proximal urethra; this begins to fall several seconds before micturition starts (Tanagho and Miller 1970). Most of the evidence quoted here is, therefore, generally in accord with the concept that micturition is initiated by relaxation of the pelvic floor, including the sphincter urethrae. Other authorities accord the initiating role to the vesical detrusor (Lapides 1969). For further information on this controversial topic, consult Boyarsky (1973).

During ejaculation, the sphincter vesicae, as well as stopping the escape of urine, also prevents the regurgitation of the semen into the bladder.

Applied Anatomy. The urethra may be ruptured, in which case extravasation of urine will complicate micturition. Extravasation most frequently occurs superficial to the perineal membrane but deep to the membranous layer of the superficial fascia. Both these layers of fascia are attached firmly to the ischiopubic rami. It is clear, therefore, that extravasated fluid cannot pass posteriorly, because the two layers are continuous with each other around the superficial transverse perineal muscles; it cannot extend laterally, on account of the connexion of these layers with the rami of the pubis and ischium; it cannot find its way into the lesser pelvis, because the opening into this cavity is closed by the perineal membrane, and, therefore, so long as this layer remains intact, the only direction in which the fluid can make its way is anteriorly into the areolar tissue of the scrotum and the penis, and thence on to the anterior wall of the abdomen. When the lesser pelvis is crushed the urethra may be ruptured between its prostatic and membranous parts; the extravasation of urine then takes place into the extraperitoneal tissue of the lesser pelvis.

(The lower urinary tract is subject to a number of congenital anomalies (*see* p. 221) which are amenable to surgical correction. For a survey of such anomalies from the standpoint of anatomy, consult Paul and Kanagasuntheram 1956.)

REPRODUCTIVE ORGANS OF THE MALE



The male genital organs include the *testes*, *epididymides*, *deferent* and *ejaculatory ducts* and *penis*, together with certain accessory glandular structures—the *seminal vesicles*, *prostate* and *bulbo-urethral glands*.

The Testes

The testes, the *primary reproductive organs* or *gonads* in the male, are suspended in the scrotum by the scrotal tissues (especially the nonstriated dartos muscles—see below), and by the structures forming the spermatic cords, the left testis usually hanging somewhat lower (about 1 cm) than its fellow. The average dimensions of the testis are from 4 to 5 cm in length, 2·5 cm in breadth and 3 cm in the anteroposterior diameter; its weight varies from 10·5 to 14 g. Each testis is of an ellipsoidal form (**8**.165), compressed laterally, and has an oblique position in the scrotum; the upper extremity is tilted anterolaterally, the lower, posteromedially. The anterior border is convex, the posterior border nearly straight, and the spermatic cord is attached to the latter.

The anterior border, the medial and lateral surfaces, and the extremities of the testis, are convex, smooth and invested by the visceral layer of the serosal tunica vaginalis by which they are separated from the parietal layer and hence scrotal tissues external to this. The posterior border receives only a partial investment from the tunica serosa. The epididymis lies along the lateral part of the posterior border.

The epididymis consists essentially of a tortuous canal which forms the first part of the efferent route from the testis. This canal is folded on itself and tightly packed into the form of a long, narrow, flattened body attached to the posterolateral aspect of the testis. It consists of a central region, or *body*, a superior enlarged *head*, and an inferior pointed end, the *tail*. The head is directly connected with the cranial pole of the testis by its *efferent ductules*;

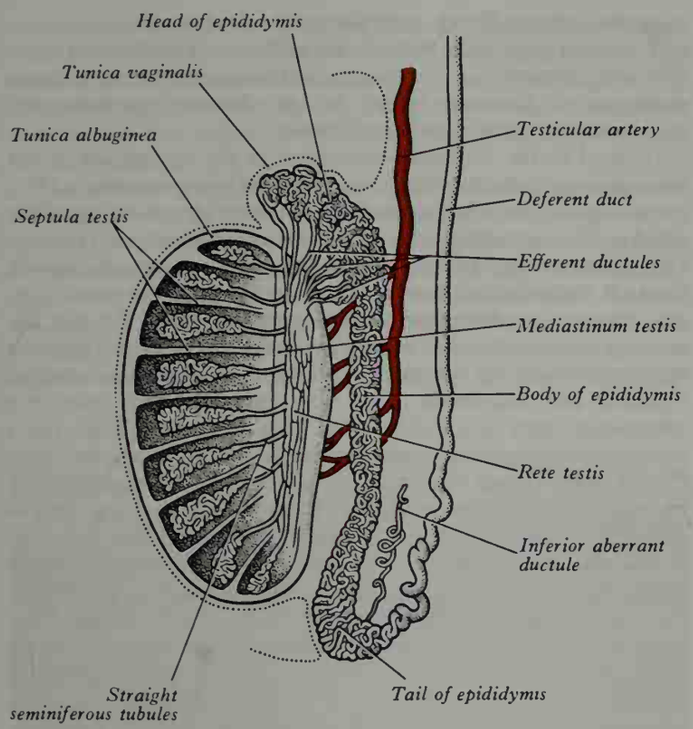
8.165 The right testis, exposed by incising and laying open the cremasteric fascia and parietal layer of the tunica vaginalis on the lateral aspect of the testis.

the tail is linked with the caudal pole by areolar tissue and a reflexion of the tunica vaginalis. The lateral surfaces of the head and tail of the epididymis are covered by the tunica vaginalis and are hence 'free'; the body is also invested by it, except along its posterior border. A recess of the tunica vaginalis, the *sinus of the epididymis*, lies between the body of the epididymis and the lateral surface of the testis.

The testicular and epididymial appendices. At the upper extremity of the testis, just inferior to the head of the epididymis, there is a minute, oval, sessile body, termed the *appendix of the testis*; it is a remnant of the upper end of the paramesonephric duct. On the head of the epididymis there is a small, stalked appendage (sometimes duplicated), the *appendix of the epididymis*, which is usually considered to be a mesonephric vestige.

The testis is invested by the tunica vaginalis, tunica albuginea and tunica vasculosa.

The tunica vaginalis (**8**.165, 171) is the inferior extremity of the processus vaginalis of the peritoneum, which, in the fetus, precedes the descent of the testis from the abdomen into the scrotum (p. 218). After the testis has reached the scrotum the cranial part of the processus vaginalis, from the internal inguinal ring to within a short distance of the testis, contracts and undergoes obliteration. The distal part remains as a closed sac, into which the testis is invaginated. It is reflected on to the internal surface of the scrotum and hence it may be described as consisting of visceral and parietal layers.



The *visceral layer* covers the lateral and medial aspects and the anterior border of the testis, but leaves most of the posterior border uncovered. At the medial side of the posterior border it is reflected forwards to become continuous with the parietal layer. At the lateral side of the posterior border it is reflected on to the medial aspect of the epididymis, lining the sinus of the epididymis, and then passes over its lateral aspect as far as its posterior border, where it is reflected forwards to become continuous with the parietal layer. The continuity between the visceral and parietal layers is established also at the upper and lower poles of the testis, but at the upper pole the visceral layer covers the upper surface of the head of the epididymis before being reflected.

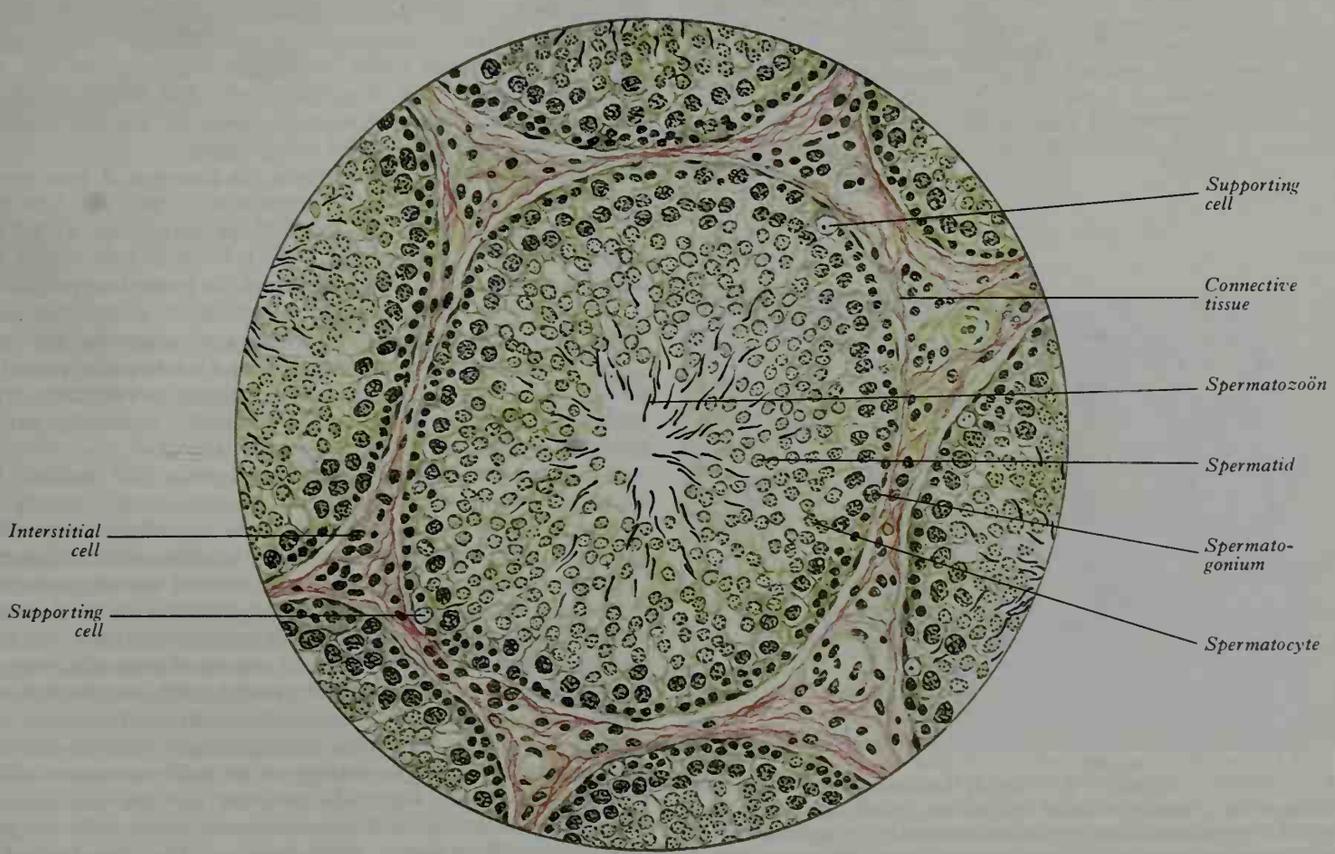
The *parietal layer* is more extensive than the visceral; it reaches below the testis and extends upwards for some distance in front and on the medial side of the spermatic cord. The inner surface of the tunica vaginalis is smooth, and covered with a layer of mesothelial cells. The potential space between the visceral and parietal layers constitutes the cavity of the tunica vaginalis.

In the embryo, the gonads (testis or ovary) project into the coelomic cavity and are covered by what for long was called the 'germinal' epithelium; some have considered that even in the adult the testis (like the ovary) is not covered by 'typical' peritoneum, the layer of mesothelium on the surface of the organ being the remnant of the original 'germinal' epithelium. The tunica vaginalis would thus be considered to consist of a parietal layer only and to become continuous with the germinal epithelium at the posterior border of the testis. Structurally, however, the parietal and visceral epithelia of the tunica are not only similar, but also like that of many areas of the general peritoneum. (Doubtless the term germinal epithelium reflects the misconception that generations of gonocytes developed from the specialized mesothelium of the gonadal or genital ridge.)

The obliterated part of the processus vaginalis may frequently be seen as a fibrous thread in the anterior part of the spermatic cord; sometimes this may be traced from the internal end of the inguinal canal, where it is connected with the peritoneum, as far as the tunica vaginalis; sometimes it is lost in the spermatic cord. In some instances the upper part of the processus vaginalis is not obliterated, and the peritoneal cavity then communicates with the tunica vaginalis; in others the proximal processus vaginalis may persist, but its distal end is shut off from the tunica vaginalis (pp. 218, 1367). Occasionally the processus may preserve its original cavity at an intermediate level as a cyst in the spermatic cord.

The tunica albuginea forms a fibrous covering for the testis. It is a dense membrane, of a bluish-white colour, composed of interlacing bundles of white fibrous tissue. It is covered externally by the visceral layer of the tunica vaginalis, except at the head and tail of the epididymis, and along the posterior border of the testis, where the testicular vessels and nerves enter the gland. It is applied to the tunica vasculosa, and, at the posterior border of the testis, is projected into its interior, forming a thick but incomplete, vertical septum, the **mediastinum testis** (**8**.166). This extends from the upper to near the lower end of the testis,

8.166 A vertical section through the testis and epididymis, showing the arrangement of the ducts of the testis and the mode of formation of the deferent duct.



and is wider above than below. From its front and sides numerous incomplete septa (*septula testis*) are given off and radiate towards the surface of the testis, where they are attached to the deep aspect of the tunica albuginea. They divide the organ incompletely into a number of cone-shaped lobules.

The bases of the lobules are at the surface of the testis, and their apices converge upon the mediastinum. Dhingra (1977) has contributed a detailed comparative account of the mediastinum testis. The arrangement of its connective tissue is very variable, and some species, including man (Holstein 1967), display nonstriated myocytes amongst the collagen fibres (*see* p. 1415). It is traversed by many vessels, and by efferent and retial tubules. Leydig cells are absent from the mediastinum testis in man, but are present in some ungulates.

The tunica vasculosa is the vascular layer of the testis, consisting of a plexus of blood vessels held together by delicate areolar tissue. It extends over the internal aspect of the tunica albuginea and covers the septa, and therefore forms an investment to all the lobules of the testis.

STRUCTURE OF THE TESTIS

The surface covering of the testis is a layer of flattened mesothelial cells similar to those which line the peritoneal cavity; by some these mesothelial cells have been considered to be remnants of a 'germinal' epithelium. The main internal architecture is formed by the *lobules of the testis* (**8**.166). Their number, in a human testis, is estimated to be between 200 and 300. They differ in size according to their position, those in the middle of the testis being larger and longer. Each lobule contains from one to three or more minute *convoluted seminiferous tubules*. When the latter have been unravelled by careful dissection under water, they are seen to commence either by free blind ends or by anastomotic loops. Clermont and Huckins (1961) and Roosen-Runge (1961) have described these tubules (in the rat) as closed loops, opening at both ends into the tubuli recti, and thence into the rete testis, a view which is now generally accepted. They are supported by loose connective tissue which contains here and there groups of *interstitial cells* (**8**.167A) containing yellow pigment granules. The total number of tubules in each testis is estimated to be between 400 and 600, and the length of each is 70 to 80 cm. Their diameter varies from 0·12 to 0·3 mm. The tubules are pale in colour in early life, but in old age they contain much fatty matter and acquire a deep yellow tinge. Each tubule (**8**.167A) consists of a basement membrane formed of laminated connective tissue containing

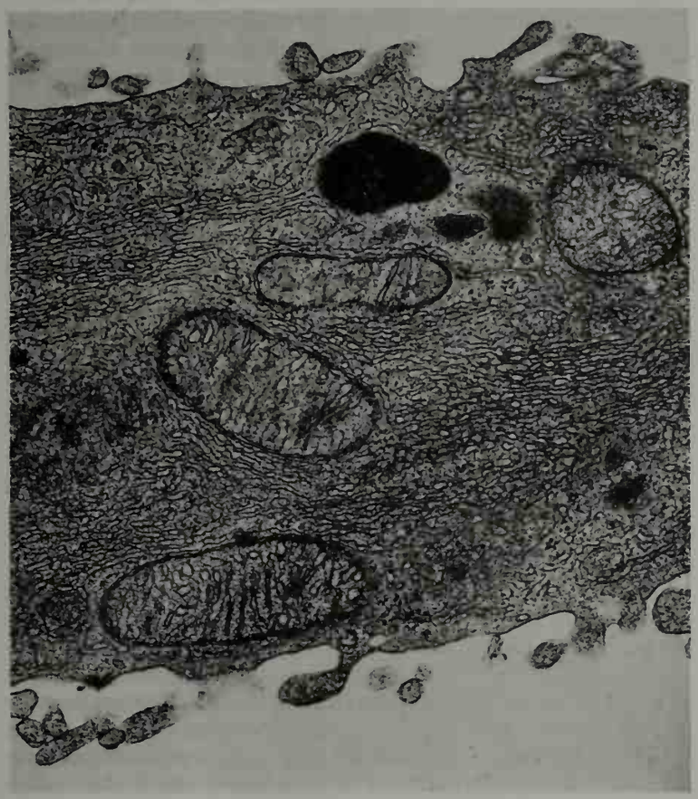
8.167A A tranverse section through a part of a human testis. Stained with iron haematoxylin and Van Gieson's stain. Magnification about ×350.

8.167B The epithelium of the seminiferous tubule in an adult man. A thin section of glutaraldehyde-fixed material, stained with toluidine blue. Spermatogonium (bottom left), primary spermatocytes (bottom right), and late spermatids (central) are visible. The spermatids are attached to a supportive cell of Sertoli (below them). For further details compare with **8.168**. (By kind permission of Doctors A. F. Holstein and U. Wulfhekel, *Andrologie*, **3**, 1971 and of the publishers, Grosse Verlag, Berlin.)

8.167C A section through the corpus of the human adult epididymis, showing deep columnar ciliated epithelium, small contractile cells, arranged circumferentially, immediately external to the epithelium, and larger nonstriated muscle cells more externally. A thin glutaraldehyde fixed section stained with toluidine blue. (Kindly supplied by Dr. A. F. Holstein, University of Hamburg. For details see H. G. Baumgarten, A. F. Holstein and E. Rosengren, *Z. Zellforsch. mikrosk. Anat.*, **120**, 1971.)

numerous elastin fibres, with flattened cells between the layers, and covered externally with a layer of flattened epithelioid cells. (For the ultrastructure of intercellular contacts between these elements, *see* Nicander 1967.) As age advances, the basement membrane becomes thicker and denser.

Internal to the basement membrane is the epithelium of the seminiferous tubule, which consists of two elements, one *spermatogenic*, the other *supportive*—in the wider meaning of the word and not merely in a mechanical sense. The former (**8.167B**, 168), when active, include an array of cells from spermatogonia through their derived forms, spermatocytes and spermatids, to the ultimate product, the mature spermatozoön. Among the spermatids there may also be *residual bodies* (pp. 96, 99). These are spherical structures containing membranous and mitochondrial residues and numerous free ribosomes, derived from the spermatids from which the bodies have separated. Their exact role in spermatogenesis is not yet clarified, despite intense study (Vaughn 1966), but they may be involved in the regulation of spermatogenesis; they undergo autolysis and perhaps phagocytosis by sustentacular cells, as mature spermatozoa are released.



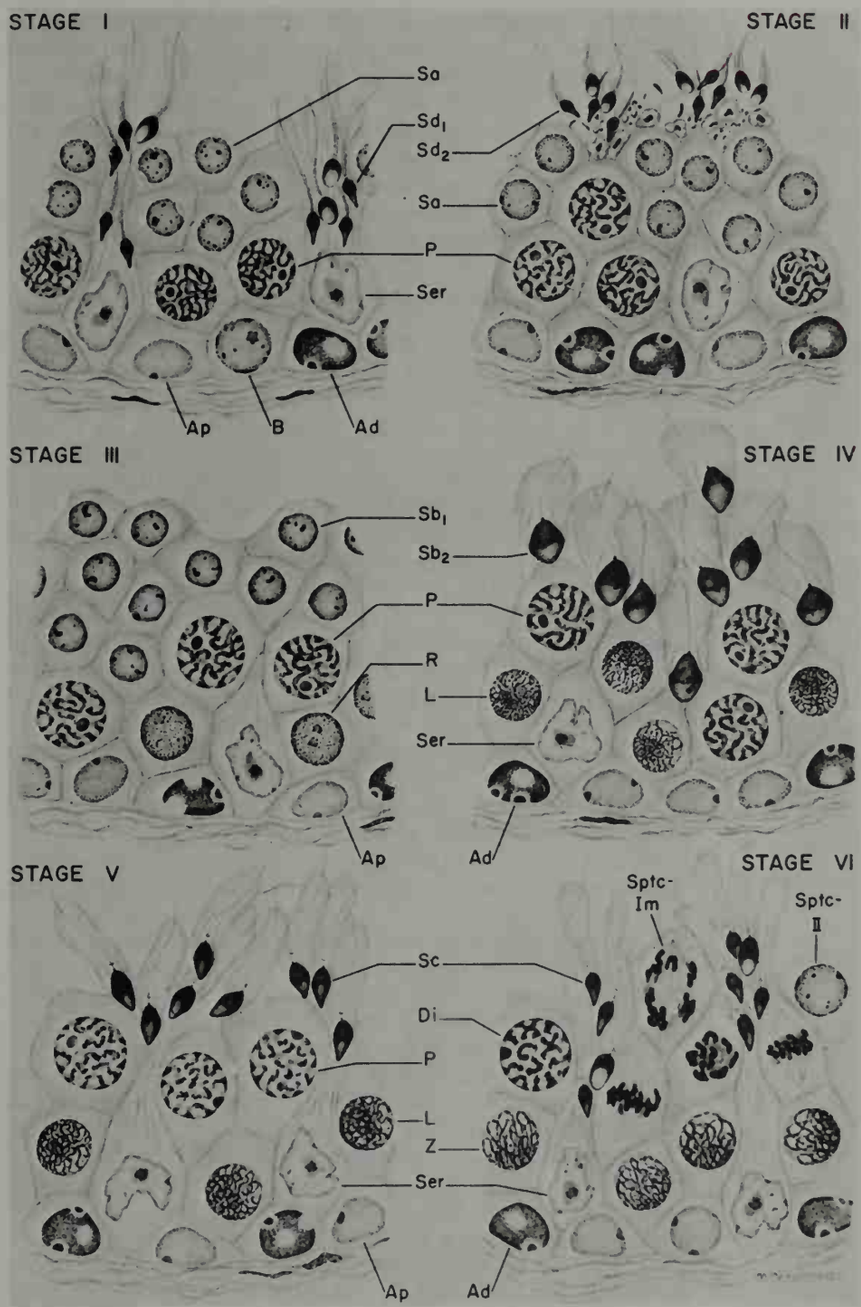
Spermatogonia are the stem cells from which all spermatozoa are derived; they themselves are descended from those primordial germ cells which reach and multiply in the genital cords of the developing testis, where they are sometimes termed *gonocytes*. In the fully differentiated testis they are sited along the basement membrane of the seminiferous tubule. Their cytological characteristics have been noted in a previous section (p. 98), as have those of the generations of spermatocytes and spermatids which are produced from them in serial cell divisions. It has been recognized since the beginning of the twentieth century that several types of spermatogonia can be recognized (Regaud 1901); and on the basis of cell and nuclear dimensions, distribution of nuclear chromatin, and histochemical and ultrastructural data, a considerable number of spermatogonial types have been identified, though there are disagreements over minor details (Courot *et al.* 1970). It may be added here that in the same manner, various stages in the maturation of spermatocytes and spermatids (p. 98) have also been recognized, so that a rather complex lineage of cells, extending from spermatogonia to spermatozoa, can now be defined step by step, and can be identified in the seminiferous tubules of most vertebrates. Mammals have been more extensively studied, however, and especially rodents and domestic cattle—the latter under the impetus of the volume of research upon the characteristics of semen engendered by artificial insemination.

The basic types of spermatogonia, the *dark type A*, *pale type A*, and *type B*, have been noted elsewhere (p. 98); the first type divides to maintain the basic store of spermatogonia, giving rise also to some *pale* type A cells, which in their turn divide and differentiate into type B spermatogonia, the immediate precursors of spermatocytes. More complex classifications of spermatogonia are, in fact, in current use; for example, a *pro-spermatogonial stage* (A_0) is recognized by most observers, and a series, designated A_1 to A_4, is utilized in describing the train of intermediate types visible in active seminiferous epithelium. Similarly, several grades of B type spermatogonia are recognized.

It is important to emphasize at this point that much of the apparent complication of the current nomenclature is merely due to successive divisions of spermatogonia, the behaviour of which can be investigated in this regard by labelling with radioactive thymidine. Such studies have been carried out extensively in primates (Clermont 1963, 1969), and there seems no reason to doubt that the findings are applicable in general to man. The dark A spermatogonia (A_1) form a resting reserve of stem cells, whereas the pale type (A_2) divide to form further A_2 cells, one of which also forms more A_2 elements while the other divides to provide two type B spermatogonia. Since the latter give rise, by repeated divisions, to several generations of cells, it is convenient to designate these as B_1, B_2, etc. In monkeys (*Cercopithecus aethiops*) five such generations of B spermatogonia occur, with the final production of *primary spermatocytes*. The number of B spermatogonial generations in man is four, and since the number of cells (without allowing for degeneration of some) is theoretically doubled at each stage, there is a basis for the

production of the very large number of spermatozoa formed during the active reproductive life of male vertebrates. The number of spermatogonial generations varies, being high in fish (six to fourteen), low in birds (one to three) and ranging from four to seven in the mammals so far investigated, (*see* p. 98 and Holstein 1976).

The primary spermatocytes, with a diploid chromosome content, divide to form **secondary spermatocytes** with a haploid complement of chromosomes; this constitutes the nuclear division designated meiosis I (*see* p. 98). In turn the secondary spermatocytes undergo the second meiotic division to form spermatids. Both types of spermatocytes and the spermatids pass through a series of changes, recognized chiefly on the basis of nuclear activities, although of course in the latter there are



8.167D A transmission electron micrograph of part of an interstitial cell of the testis (Leydig cell) showing the profuse agranular endoplasmic reticulum and prominent mitochondria (murine). (Magnification ×20,000.)

profound accompanying modifications in the soma of each spermatid to reach the mature flagellated spermatozoön.

The primary spermatocyte passes through a resting or *proleptotene* stage, followed by identifiable leptotene, zygotene, pachytene and diplotene stages (*see* p. 98), and the completion of cell division. The secondary spermatocytes divide much more rapidly into spermatids.

The spermatids gradually mature into spermatozoa through a series of nuclear and cytoplasmic modifications (*see* p. 99), and several stages have been identified on the basis of nuclear shape, 'round' and 'elongating' spermatids being generally recognized. With their formation, spermatogenic multiplication is usually regarded as coming to an end. Thus, it will be appreciated that the spectrum of identifiable cell types in the seminiferous epithelium is of considerable complexity, and to this must be added the supportive element in the epithelium.

The sustentacular or supporting cells (of Sertoli), or *sustentocytes*, are the only non-germinal individuals in the complex cell population of the seminiferous tubules. They are somewhat polymorphic cells, both in nuclear and somatic characteristics. They have been the subject of much controversy, and in the developing seminiferous tubules a variety of types of supporting cells, which do not fall within the 'Sertolian' category, are also identified. It is, however, generally assumed that almost all the non-germinal cells in the tubules of the adult, functioning mammalian testis are of this limited type. Such sustentacular cells are sited on the limiting membrane of the tubules, occupying it almost to the exclusion of all but occasional spermatogonia. In tangential sections they are polygonal cells, in transverse sections somewhat irregular, but approximately columnar. Their apical profiles are, however, much complicated by recesses into which the spermatids and spermatozoa fit until the latter are mature enough for release; and long cytoplasmic processes also extend among the spermatogonia and spermatocytes. This arrangement strongly suggests that the sustentacular cells maintain structural cohesion between the varied elements of the epithelium. Electron microscopy (Fawcett 1975) has disproved the once strongly held

8.168 The cycle of spermatogenesis in the human seminiferous tubule. For details of the six stages see accompanying text. Ser=sustentacular cells of Sertoli. view that these cells formed a syncytium, revealing that their contiguous surfaces are in fact held together by a variety of specialized contacts superficially similar to 'tight' junctions (*see* p. 7), but of at least three types (Nicander 1967; Flickinger and Fawcett 1967). (Sertoli, himself, demonstrated the individual nature of these cells in 1865.) The nucleus is irregular, often indented, and weakly positive to Feulgen staining. It contains one or two pyroninophilic nucleoli, and these may be tripartite, consisting of a nucleolonema (*see* p. 27) and two associated electron-dense bodies (see also the general description of nucleolar structure on p. 27). The cytoplasm contains abundant organelles, particularly mitochondria, endoplasmic reticulum, secretion granules, Golgi complexes, ribosomes, microfilaments and microtubules. The last named form, presumably, a kind of cytoskeleton and may also be a factor in the cohesive effect of the sustentacular cells on other epithelial units. These and other details also suggest that these cells exercise a metabolic influence in relation to the germinal elements; they are in addition considered to be phagocytic (Carr *et al.* 1968) and perhaps to exert an endocrine influence. They themselves undergo considerable changes during the spermatogenic cycle (*vide infra*) and are influenced by the hypophysial hormones, LH and FSH. They also play a part in the mechanisms of the '*blood-testis barrier*'. For a recent general review of these and other aspects of testicular structure and physiology consult Johnson and Gomes (1977).

THE SPERMATOGENIC CYCLE

The numerous elements of the seminiferous epithelium briefly described above constitute an intimately related population of cells which is in a continuously dynamic state, the parameters of which have been extensively investigated, not only in a range of laboratory animals (particularly the rat), but also in animals of commercial or 'domestic' importance, and in man. In addition to a wealth of information regarding the cytological progression from spermatogonia to spermatozoa, various quantitative aspects of this cycle of changes have been assessed, including the timing of various phases of the process, the relative numbers of different forms of germinal cells at definable points in this temporal sequence, and so on. Cytological studies have clearly established that at any specified locus in a seminiferous tubule the activities in the several generations of germinal cells (identifiable as described above), and hence the overall qualitative and quantitative associations of cell types, pass through a *cycle*, the length of which and the number of stages involved vary in different species (Clermont 1972). The cycle occupies 12 to 13 days in rats, but only 8·6 in the mouse; in monkeys (Arsenieva *et al.* 1961) the figure is 10·5 to 11·6 days, and about 16 in mankind (Heller and Clermont 1964). The number of stages recognized has been established on a surer basis by two methods of classification, one involving the development of the acrosomal system of the spermatids (Leblond and Clermont 1952), the other based upon morphological changes in germ cell nuclei (Roosen-Runge and Giesel 1950). Both methods were originally elaborated in rats, but have also been applied to many other mammals and some birds, and also to man. The two methods yield figures of fourteen and eight stages in the rat; the *acrosomalic technique* leads to identification of only six stages in man, and these will shortly be detailed. In many mammals all parts of the circumference of a short length of seminiferous tubule are observed to be in the same stage, while adjoining cylindrical regions display the numerically preceding or succeeding stages. All stages can thus be recognized in succession along the tubules, the last stage being followed by a cylinder of activity in the first stage. Of course, each annular locus itself passes through all stages and then begins again, so that there exists not only a *local* succession of stages, spread over the characteristic period of the cycle in the species involved, but also a procession of stages, which appears to move in an undulatory manner along the tubule. Such a '*spermatogenic wave*' has been measured in some species (for example, the rat and bull—*see* Mochereau 1963), but the 'wave-length' has been found to be irregular and subject to modifications. In man, not even all quadrants of a local cylinder of seminiferous epithelium are in the same cyclic phase at any one time. These stages are as follows (**8**.168).

Stage I is typified by the presence of two generations of spermatids—a newly formed one with spherical nuclei, and an older one with elongating nuclei. These latter cells are deeply invaginated in groups into the cytoplasm of sustentacular cells. Associated with them are primary spermatocytes at the start of the lengthy pachytene stage of the prophase of the first meiotic division; A (dark and pale) and B type spermatogonia are arranged close to the basement membrane.

Stage II also contains two stages of spermatid maturation, but these are further advanced, and the older spermatids are close to final modification into spermatozoa, and hence the presence of residual bodies. The primary spermatocytes are still in the pachytene stage, but the B type spermatogonia have now appeared in greater numbers amongst the dark and pale A types.

Stage III. The older spermatids have reached the end of spermatogenesis and are released as spermatozoa (spermiation). Nearest to these is a single generation of well-advanced spermatids, external to which are two generations of primary spermatocytes, the older still in the pachytene stage, with younger cells in the proleptotene or resting stage of meiosis. Type A spermatogonia predominate, the type B having become spermatocytes.

Stage IV. Spermatid nuclei are commencing to elongate, but are irregular in shape. The older primary spermatocytes are in the pachytene stage and the younger ones are moving into the leptotene stage. Type A spermatogonia are gathered external to the above cells.

Stage V. Groups of spermatids display elongated nuclei orientated centrifugally towards the periphery of the tubule. The primary spermatocytes are now in the *late* pachytene condition, and some in the leptotene stage.

Stage VI. Groups of maturing spermatids are visible between primary spermatocytes undergoing division into secondary spermatocytes. Some of the latter are seen in the interphase stage, and external to them are primary spermatocytes in the zygotene stage. Type A spermatogonia (pale and dark) now predominate again close to the basement membrane.

The details of these stages may seem a little complex, but they fit into the succession of divisions and differentiations known to occur in the germinal cell series. The process appears much less regular, particularly in human biopsy material, perhaps in part due to mechanical disturbance. In addition, an unknown number of cells undergo retrogression and degeneration.

The epithelium of the seminiferous tubule is perhaps unique in its organization (Fawcett 1975), consisting, as it does, of a permanent population of non-proliferative Sertoli or sustentacular cells, sessile upon its basement membrane, and, interspersed amongst these, the proliferating spermatogonia and their derivatives. The latter are related to the basal parts of the Sertolian cells, the lateral junctions of which (**8**.167B) are now considered to create a '*basal compartment*', in which are the preleptotene spermatocytes. These junctions must at some point break down to allow the spermatocytes to move up towards the tubular lumen and into a so-called '*adluminal compartment*'. It is suggested that in primates the 'blood-testis barrier' resides in these modifiable junctions, which may be under hormonal control. This implies that, whereas the spermatogonia and early spermatocytes are directly accessible to all substances transported across the capillary wall, the later spermatocyte stages and spermatids are screened from substances incapable of passing the 'barrier'. As the spermatids mature they move up towards the lumen from the lateral aspects of Sertolian cells, at first embedded largely in the cytoplasm of the latter and attached by a junctional specialization which itself undergoes a series of changes (Ross 1976) until the spermatozoa are released into the lumen of the seminiferous tubule.

THE EFFERENT DUCTULES AND EPIDIDYMIS

The events described in the preceding section occur in the highly coiled part of the seminiferous tubules. As they reach the apices of their lobules, they become less convoluted, assume an almost straight course, and unite to form twenty to thirty larger straight ducts, about 0·5 mm in diameter (**8**.166).

The straight seminiferous tubules enter the fibrous tissue of the mediastinum, and pass upwards and backwards, forming, in their ascent, a close network of anastomosing tubes lined by flattened epithelium; this network is named the *rete testis*. At the upper end of the mediastinum these tubes terminate in from twelve to twenty ducts, termed the *efferent ductules*; they perforate the tunica albuginea, and pass from the testis to the epididymis. Their course is at first straight; then they become enlarged and exceedingly convoluted, and form a series of conical masses, known as the *lobules of the epididymis*, which together form the head (caput) of the epididymis. Each lobule consists of a single convoluted duct, from 15 to 20 cm in length. Opposite the bases of the lobules the ducts open into a single canal, the *duct of the epididymis*, whose complex convolutions form the body (corpus) and tail (cauda) of the epididymis. When the convolutions are unravelled, this tube measures upwards of 6 m in length; it increases in diameter and thickness as it approaches the tail of the epididymis where it becomes the deferent duct. The convolutions are held together by fine areolar tissue, and by bands of fibrous tissue. It is to be noted that the body and tail of the epididymis consist of a single tube.

The efferent ductules are lined by ciliated columnar epithelium and have a thin circular layer of nonstriated myocytes in their walls. In the duct of the epididymis the muscle coat becomes thicker and the epithelium is columnar pseudostratified, the superficial cells having long (15 μm) regular microvilli with a diameter of about 0·2 μm. Because of their superficial resemblance to cilia these structures are often termed '*stereocilia*', but they lack the characteristic ultrastructural details of true cilia. Tracer experiments have demonstrated the uptake of proteins by the cells of the efferent ductules by phagocytic vesicle formation. It seems likely that these cells modify the composition of seminal fluid. Electron microscopic studies have revealed inclusion bodies in the nuclei of the epithelial cells of the human epididymis (Horstmann 1962, 1966). In man fragments of ingested spermatozoa have also been observed in small round cells, with their cytoplasmic processes projecting into the duct of the epididymis (Holstein 1967). In several experimental animal species the localization of lysosomal enzymes supports the hypothesis of an absorptive function in the epididymal epithelium (Moniem and Glover 1972).

Further studies (Baumgarten *et al.* 1970) suggest that three ultrastructurally distinguishable types of contractile cell occur in both the ductules and the epididymis. These cells receive only a sparse adrenergic innervation, and few of the nerve fibres penetrate between the nonstriated myocytes (in contrast to the more profuse innervation of the nonstriated muscle of the caput epididymis and ductus deferens). These morphological differences accord with the slow, spontaneous and local contractions of the ductules and proximal epididymis, and the rapid, reflex contractions of the caput and ductus during emission.

THE TESTICULAR INTERSTITIAL TISSUE

The interstitial cells of the testis, usually equated with the *cells of Leydig* (1850), also include various other cells, some of connective tissue type, together with the vessels and nerves in the tissue between the seminiferous tubules. The origin of the specific interstitial cells (of Leydig) is probably mesenchyme, but it is also suggested that they arise from the mesonephric blastema (Witschi 1951). These cells, isolated or clustered, occur in the intertubular tissue of most vertebrates, including man. They are large, polyhedral cells with an eccentric nucleus containing one to three nucleoli, and they possess scanty, poorly staining cytoplasm (Hooker 1971). They contain (**8**.167D) much agranular endoplasmic reticulum (rich in ascorbic acid), vacuoles containing fats, phospholipids and cholesterol, resembling in such features the interstitial cells of the ovary (p. 1424), the luteal cells of the corpus luteum (p. 1424), and cells in the adrenal cortex (p. 1457). Their masculinizing effect was demonstrated almost eighty years ago (Bouin and Ancel 1903), but doubt as to whether they are the sole source of testicular androgens is not yet entirely removed. Most of the experimental evidence demonstrates the lack of endocrine function of this kind in the tubules, rather than proving that the interstitial cells are the sole source of androgens. However, it is generally accepted that they do secrete androgens, and that no other function can at present be attributed to them (Christensen 1975). They are themselves stimulated into activity by the interstitial cell stimulating hormone (ICSH—identical with LH) and possibly follicle stimulating hormone (FSH) of the anterior lobe of the hypophysis cerebri (p. 1439). In cryptorchidism, where the testes are retained in the inguinal canal and hence subjected to a warmer environment, the rate of production of androgens, as well as of spermatozoa, is depressed, without, however, any recognized cytological changes in the interstitial cells. Androgens stimulate the growth and activity of the male accessory reproductive glands (prostate, seminal vesicles and bulbo-urethral glands) and also the secondary sexual changes at puberty—growth of facial, axillary and pubic hair, enlargement of larynx and paranasal air sinuses, and the additional skeletal growth characteristic of the male. Most of these changes are inhibited by oestrogens (in sufficient amounts), especially when androgenic output is depressed, as occurs in some eunuchoid conditions. (*See* also p. 1439.)

The proportion of interstitial cells (of Leydig) to the other components of the intertubular tissue displays variations at different ages, and in certain clinical conditions. After an initial period of multiplication in early fetal life, they appear to atrophy around the time of birth, though there is some disagreement as to whether they actually disappear or are merely depressed in number in the immediate post-natal period (Cooper 1929; Sohval 1954). It is generally agreed that they reappear in the prepubertal period, perhaps developing from mesenchyme cells (Hisakayu and Harrison 1971). There is no reduction in the numbers of Leydig cells in the elderly (55–65 years) according to Kothari and Gupta (1974). In cryptorchid testes these cells are absent, while the total amount of intertubular tissue is increased. For techniques of quantitative assessement of Leydig cells in human and other mammalian testes consult papers by Dykes (1969); Heller *et al.* (1971); Christensen (1975); and Kothari *et al.* (1978).

THE TESTICULAR CAPSULE

The coverings of the testis have already been noted (p. 1410); they may be briefly summarized, proceeding from the surface internally, as the skin, dartos muscle, superficial perineal fascia, external and internal spermatic fasciae with the cremasteric fascia interposed, the parietal layer of the tunica vaginalis, the capillary interval between this and the visceral layer, the tunica albuginea and tunica vasculosa. The last three strata form the so-called '*testicular capsule*', a concept which has become of considerable significance as a result of the reported demonstration of a contractile element in what is usually regarded as an inert and largely fibrous tissue structure (Davis and Langford 1969). In rabbits and rats isolated preparations of the testicular capsule can be made, and these show spontaneous contractions and also react to both cholinergic and adrenergic agents. Abundant autonomic nerve endings in relation to blood vessels have been described in the tunica albuginea (Norberg *et al.* 1967), and nonstriated muscle cells have been demonstrated in the tunica in various rodents and in man (Holstein 1967). The distribution of such muscle fibres varies, and while they are widely scattered in the human tunica albuginea, they are concentrated chiefly in a posterior position, adjacent to the epididymis. The role of the contractile testicular capsule is most probably to massage or pump the duct system of the testis, and thus to impel spermatozoa in an onward direction. For a review of the pertinent literature, consult Davis *et al.* (1971).

TEMPERATURE REGULATION AND THE TESTIS

The testes are external or *scrotal* in most marsupials and eutherians, but *abdominal* in fish, amphibians, reptiles, birds and monotremes. There are some exceptions amongst mammals: the testes are abdominal in location in sloths, elephants and hyraces. In aquatic mammals they are either abdominal (whales and dolphins) or close to the body in the inguinal region (seals). In some mammals they are scrotal in position during the breeding

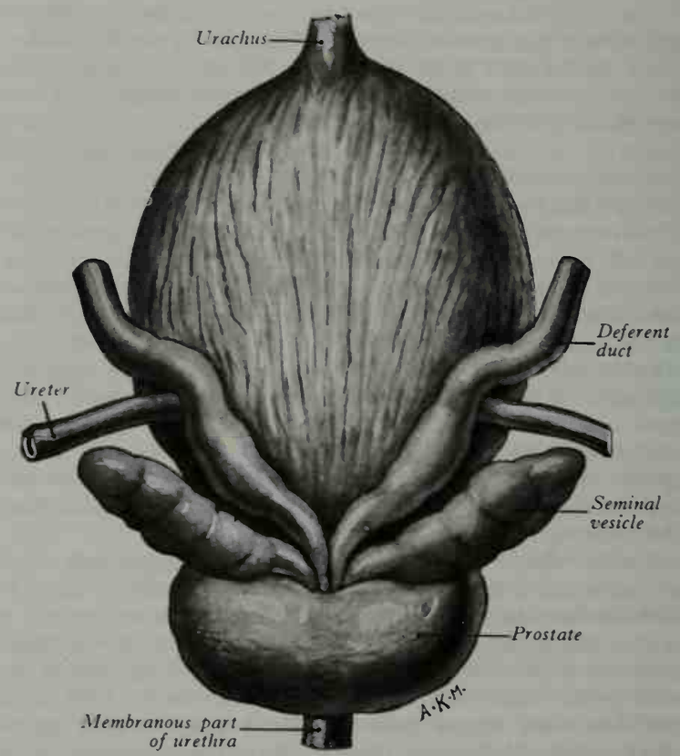
season, but inguinal or even abdominal in position at other times (rodents, bats and insectivores). The variations in mammals are puzzling, but there is a general assumption that the predominance of scrotally suspended testes in mammals is associated with their homeothermic specialization, though this does not explain the abdominal testes of birds. The regulation of the internal body temperature (Hammel 1968) appears to create, in general, too warm an environment for spermatogenesis; and experimental evidence, reviewed by Bishop and Walton (1960), amply confirms this general concept. The scrotal temperature is usually several degrees below that of the abdomen (three degrees in man), but obviously the optimum range for spermatogenesis—though lower—must also be maintained. The mechanisms involved in this are numerous (Waites 1970), and the factors concerned in testicular thermoregulation can merely be mentioned here. The scrotal skin is usually hairy, but this potential heat-conserving covering is most variable: it is scant in man, profuse in marsupials. Sweat glands are well developed and usually numerous, but subcutaneous fat is generally absent. The radiant area of the scrotal skin, which is well vascularized, can be much reduced in colder conditions by contraction of the dartos muscle, probably by direct stimulation, or perhaps by local reflexes. The primate scrotal skin contains many nerve endings which respond to chilling or to warming, the latter being more numerous (Iggo 1969). The cremaster muscles, by elevating the testes closer to the perineum, may assist in conserving heat. A form of *countercurrent heat exchange* is considered to occur between the arteries and veins of the spermatic cord, where they are both considerably coiled and in close apposition (Harrison and Weiner 1949). In dogs experiment has shown that the blood delivered to the testis is pre-cooled by 3 °C. by this mechanism (Waites and Moule 1961). There is increasing evidence that in addition to heat, respiratory gases and a number of other substances (including labelled testosterone and prostaglandin-F), can be transferred between these arteries and veins, in several species, including man. (For discussion of the literature *see* Free 1977.)

There thus exists a surprising array of factors concerned in testicular thermoregulation and the maintenance of fertility; and while these appear to be jointly involved in this particular function, there are suggestions, at least, that the scrotum may also act as an agent in the reciprocal control of general body temperature.

Vessels and Nerves

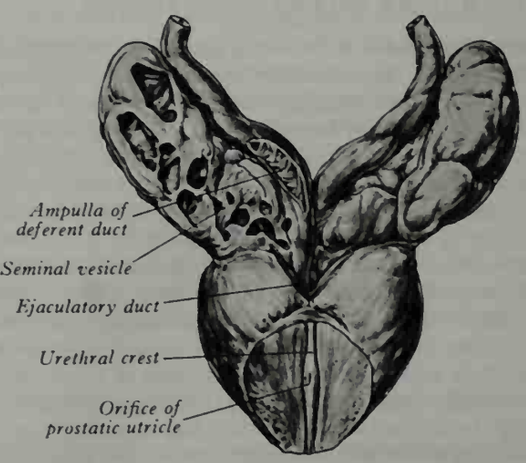
The *testicular artery* is described on p. 718 and the *testicular veins* on p. 762. The intratesticular course of the arterial supply has received much attention in man (Hundeiker and Keller 1963). In a recent study (Kormano and Suoranta 1971), marked coiling of the arteries was noted; the capillaries adjoining the seminiferous tubules penetrate the layers of the interstitial tissues. These capillaries have acquired a particular interest as a part of the anatomical site of the 'blood-testis barrier' (Setchell and Waites 1975; Neaves 1977). The capillaries run either parallel to the tubules or transversely across them; they do not enter the walls of the seminiferous tubules, being separated from the germinal and supporting cells by a basement membrane, and by variable amounts of interstitial tissue containing Leydig cells. It is at this level that highly interesting selective exchange phenomena occur in connexion with androgens and immune substances.

The *lymph vessels* of the testis end in the lateral and pre-aortic lymph nodes (p. 797).



The *nerves* accompany the testicular vessels, and are derived from the tenth and eleventh thoracic segments of the spinal cord, through renal and aortic autonomic plexuses (pp. 1131, 1134). Catecholamine-containing nerve fibres have been identified in the human testis and epididymis. Such fibres form plexuses around smaller blood vessels and amongst the interstitial cells (Baumgarten and Holstein 1967). For a review of testicular innervation, consult Hodson (1970).

Applied Anatomy. At an early period of fetal life the testes are located in the posterior part of the abdominal cavity. Their descent into the scrotum is described on p. 217. The descent appears to be under hormonal control (gonadotropins and androgens). In the scrotum the testes are in a cooler environment than that in the abdomen, and it is believed that the lower temperature favours spermatogenesis (*vide supra*).



The descent of the testis may be arrested. It may be retained in the abdomen; or it may be arrested at the deep inguinal ring, or in the inguinal canal; alternatively it may just emerge from the superficial inguinal ring without reaching the bottom of the scrotum. The retained testis is probably reproductively useless; so that a man in whom both testes are retained (*anorchism*) is sterile, though he may not be impotent. The absence of one testis is termed *monorchism*. When a testis is retained in the inguinal canal the situation is often complicated by a co-existent congenital hernia, the processus vaginalis of the peritoneum remaining patent. The testis may descend through the inguinal canal, but may miss the scrotum and assume some abnormal position (*ectopia testis*, p. 218).

The testis may be inverted within the scrotum so that its posterior or attached border is anterior and the tunica vaginalis is posterior.

Fluid collections of a serous character frequently occur in the

8.169 Posterosuperior aspect of the male internal urogenital organs.

8.170 Anterior aspect of the seminal vesicles, terminal parts of the deferent ducts, and the prostate. The lamina of the right seminal vesicle, the ampulla of the right deferent duct, and of the prostatic part of the urethra have been exposed by appropriate removal of tissues.

scrotum. To these the term *hydrocele* is applied. The most common form is the ordinary *vaginal hydrocele*, in which the fluid is contained in the sac of the tunica vaginalis. In another form, the *congenital hydrocele*, the fluid is in the sac of the tunica vaginalis, but this sac communicates with the general peritoneal cavity, owing to non-obliteration of the proximal part of the processus vaginalis. A third variety, known as an *infantile hydrocele*, occurs in those cases where the processus vaginalis is obliterated only at or near the deep inguinal ring. It resembles the vaginal hydrocele, except as regards its shape, the collection of fluid extending up the cord into the inguinal canal. Fourthly, the processus vaginalis may be obliterated both at the deep inguinal ring and above the epididymis, leaving a central unobliterated portion, which may become distended with fluid, giving rise to a condition known as *encysted hydrocele of the cord*.

Encysted hydrocele of the epididymis, or *spermatocele*, is the name given to a cyst found in connexion with the head of the epididymis. Among its contents may be found a varying number of spermatozoa, and it is probably a retention cyst of one of the tubules.

The Ductus Deferens (Vas Deferens)

The deferent duct (ductus or vas deferens) is the continuation of the duct of the epididymis (**8**.166). Commencing at the tail of the epididymis, it is at first very tortuous, but, becoming gradually straighter, it ascends along the posterior border of the testis and the medial side of the epididymis. From the superior pole of the testis it runs upwards in the posterior part of the spermatic cord, and traverses the inguinal canal to the deep inguinal ring. Here it leaves other structures of the spermatic cord, curves round the lateral side of the inferior epigastric artery, and ascends for about 2·5 cm anterior to the external iliac artery. It is next directed backwards and slightly downwards, and, crossing the external iliac vessels obliquely, enters the lesser pelvis, where it continues posteriorly between the peritoneum and the lateral wall of the pelvis, and on the medial side of the obliterated umbilical artery, the obturator nerve and vessels, and the vesical vessels (**8**.159). It then crosses the ureter (**8**.169), and, reaching the medial side of this tube, bends at an acute angle, and runs medially and slightly forwards between the posterior surface of the bladder and the upper end of the seminal vesicle. Reaching the medial side of the seminal vesicle, it is directed downwards and medially in contact with it, and gradually approaches the opposite duct. Here it lies between the base of the bladder and the rectum, from which it is separated by the rectovesical fascia. Lastly, it passes downwards to the base of the prostate, and is joined at an acute angle by the duct of the seminal vesicle to form the ejaculatory duct (**8**.170). Owing to the thickness of its wall relative to the small size of its lumen, the deferent duct feels hard and cord-like when grasped by the finger and thumb. Its lumen in the greater part of its extent is of very small calibre, but posterior to the bladder it becomes dilated and tortuous, as the *ampulla*; its terminal part, which joins the duct of the seminal vesicle, is again greatly diminished in calibre (**8**.169).

Aberrant ductules. A narrow blind tubule, the *caudal aberrant ductule*, frequently occurs, and is connected with the caudal part of the duct of the epididymis, or with the commencement of the deferent duct. Its length, when it is uncoiled, varies from 5 to 35 cm, and it may be dilated towards its blind extremity, or may be of uniform diameter throughout. Its structure is similar to that of the deferent duct. Occasionally it is found unconnected with the epididymis. A second tubule, termed the *rostral aberrant ductule*, occurs in the head of the epididymis, and is connected with the rete testis. These aberrant ductules are derived from mesonephric tubules (p. 213).

Paradidymis. This term is applied to a small collection of convoluted tubules, situated anteriorly in the inferior region of the spermatic cord superior to the head of the epididymis. These tubes are lined with ciliated columnar epithelium, and probably represent the remains of a part of the mesonephros (p. 213).

Structure. The wall of the deferent duct has the usual layers of such tubes—external areolar, intermediate muscular, and internal mucosal. The muscular tunic is thick and of nonstriated fibres, arranged as an external longitudinal stratum and an internal circular one. There is also an internal longitudinal layer at the commencement of the duct. All the muscle strata intermingle to a marked extent. The internal mucous tunic is arranged in longitudinal folds. The epithelium is columnar and non-ciliated through most of the duct; a variable section towards the distal end of the duct has a bilaminar epithelium of columnar cells, the superficial tier displaying non-motile stereocilia. Many of the columnar epithelial cells are secretory in nature, and for histochemical studies on their secretory activies consult Wendler (1968).

The deferent duct is supplied by a specific vessel, the artery of the ductus deferens (p. 720), usually derived from the superior vesical artery. It anastomoses with the testicular artery, and thus forms part of the vascular supply to the epididymis and testis. The anastomosis is of special interest in connexion with the toxic effects of cadmium on the mammalian testis (*see* Gunn and Gould 1975, and Johnson 1977, for literature). These effects appear to be due to interference with vascularization, but in this respect, the artery to the ductus deferens (in rats) is apparently immune.

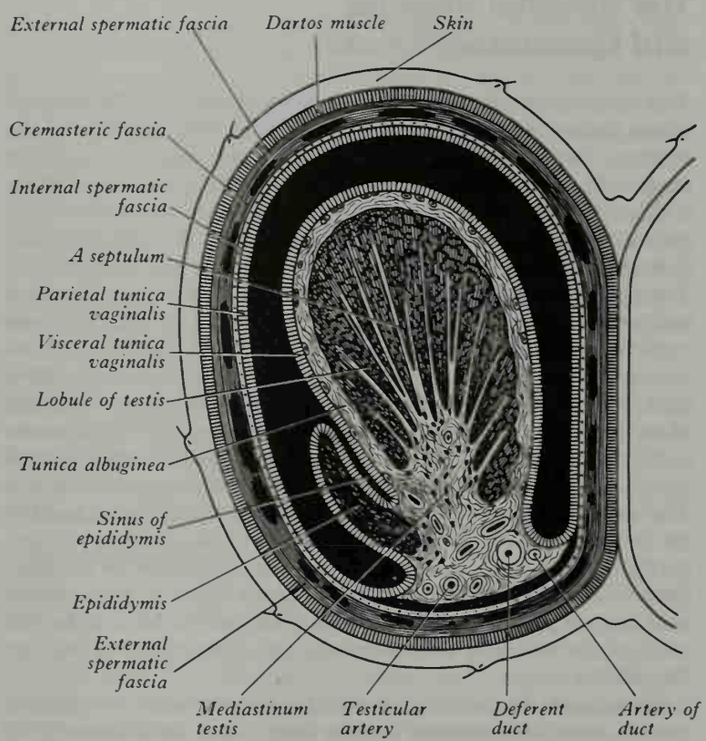
The Seminal Vesicles and Ejaculatory Ducts

The seminal vesicles (**8**.169) are two sacculated and contorted tubes, placed between the posterior surface of the bladder and the rectum. Each vesicle is about 5 cm long, and is somewhat pyramidal in form, the base being directed backwards, upwards and laterally. It consists of a single tube, coiled upon itself, and giving off several irregular diverticula (**8**.170); the separate coils, as well as the diverticula, are connected together by fibrous tissue. The tube has a diameter of 3–4 mm and its length when uncoiled varies from 10 to 15 cm; it ends above in a cul-de-sac; its lower extremity becomes constricted into a narrow straight duct, which joins with the corresponding deferent duct to form the ejaculatory duct. The *anterior surface* is in contact with the posterior surface of the bladder, extending from near the termination of the ureter to the base of the prostate. The *posterior surface* is in relation with the rectum, from which it is separated by the rectovesical fascia. The vesicles diverge from each other superiorly, and are related to the deferent ducts and the terminations of the ureters, and are partly covered with peritoneum; each is enveloped in a dense, fibromuscular sheath. Along the medial margin of each vesicle runs the ampulla of a deferent duct. Lateral to the vesicle, the veins of the prostatic venous plexus pass posteriorly to join the internal iliac vein.

Structure. The seminal vesicles have three tunics: an external *areolar*; a middle *muscular*, thinner than that of the deferent duct and arranged in two layers, an external longitudinal and an internal circular; and an internal *mucosal* tunic, which has a reticular structure. The epithelium is columnar, and in the diverticula occur goblet cells, the secretion of which forms a large part of the seminal fluid. The secretion is lightly alkaline, and contains fructose (which supplies the energy requirements of the sperms) and a coagulating enzyme (vesiculase). The seminal vesicles do not form a reservoir for spermatozoa. The latter, passing from the testis, are stored in the epididymis (and possibly in the ampulla of the deferent duct). The vesicles contract during ejaculation and their secretion forms the bulk of the ejaculated fluid.

Electron microscopy of human seminal vesicle mucosa has revealed a second type of epithelial cell amongst the columnar cells. This is a small stellate cell, usually sited between the basal parts of the columnar cells, which contains few cytoplasmic organelles. The columnar cells carry microvilli on their luminal surfaces, contain numerous mitochondria, well-developed granular endoplasmic reticulum, and a Golgi apparatus characterized by numerous secretory vacuoles (Riva 1967).

Vessels and Nerves



The *arteries* supplying the seminal vesicles are derived from the inferior vesical and middle rectal arteries. The *veins* and *lymph*

vessels accompany the arteries. The *nerves* are derived from the pelvic plexuses.

Applied Anatomy. The seminal vesicles can be palpated from the rectum. Abscesses of the seminal vesicle may rupture into the peritoneal cavity.

The ejaculatory ducts (**8**.159, 170), one on each side of the median plane, are formed by the union of the duct of a seminal vesicle with the terminal part of a deferent duct, and are nearly 2 cm long. They commence at the base of the prostate, run antero-inferiorly between the median and right (or left) lobes, pass along the sides of the prostatic utricle, and end on the colliculus seminalis in slit-like orifices on, or just within, the margins of the opening of the utricle (p. 1408). The ducts diminish in size, and also converge, towards their terminations.

Structure. The walls of the ejaculatory ducts are thin. They contain: an *outer fibrous layer*, which almost entirely disappears beyond the entrance of the ducts into the prostate, then non-striated myocytes consisting of a thin outer circular, and an inner longitudinal layer, a *mucous membrane* covered with columnar epithelium. For a detailed description of the ejaculatory musculature, *see* Schlager (1967).

8.171 A diagrammatic transverse section through the left half of the scrotum and the left testis. The tunica vaginalis is represented as artificially distended to show its visceral and parietal layers.

The Spermatic Cord and its Coverings

When the testis descends through the abdominal wall into the scrotum, it carries its vessels and nerves and the deferent duct with it. These structures meet at the deep inguinal ring and together form the *spermatic cord*, which suspends the testis in the scrotum, and extends from the deep inguinal ring to the posterior border of the testis; the left spermatic cord is a little longer than the right. Between the superficial inguinal ring and the testis the cord is anterior to the rounded tendon of the adductor longus, and is here crossed anteriorly by the superficial external pudendal artery and posteriorly by the deep external pudendal artery.

The spermatic cord traverses the inguinal canal (p. 559) having the walls of the canal as its relations, with the ilio-inguinal nerve inferior to it. In passing through the canal it acquires coverings from the layers of the abdominal wall. These coverings extend downwards into the wall of the scrotum and are named the internal spermatic, cremasteric and external spermatic fasciae.

The *internal spermatic fascia* is a thin layer which loosely invests the spermatic cord, and is derived from the transversalis fascia (p. 559).

The *cremasteric fascia* encloses some striated muscular fasciculi, united to one another by areolar tissue; the muscular fasciculi constitute the cremaster and are continuous with the obliquus internus abdominis (p. 555).

The *external spermatic fascia* is a thin fibrous stratum continuous superiorly with the aponeurosis of the obliquus externus abdominis, and descending from the crura of the superficial ring (p. 553).

Structure of the spermatic cord. The spermatic cord is composed of arteries, veins, lymph vessels, nerves and the deferent duct, connected together by areolar tissue.

The *arteries* of the spermatic cord are the testicular (p. 718), cremasteric (p. 724) and deferential (p. 720).

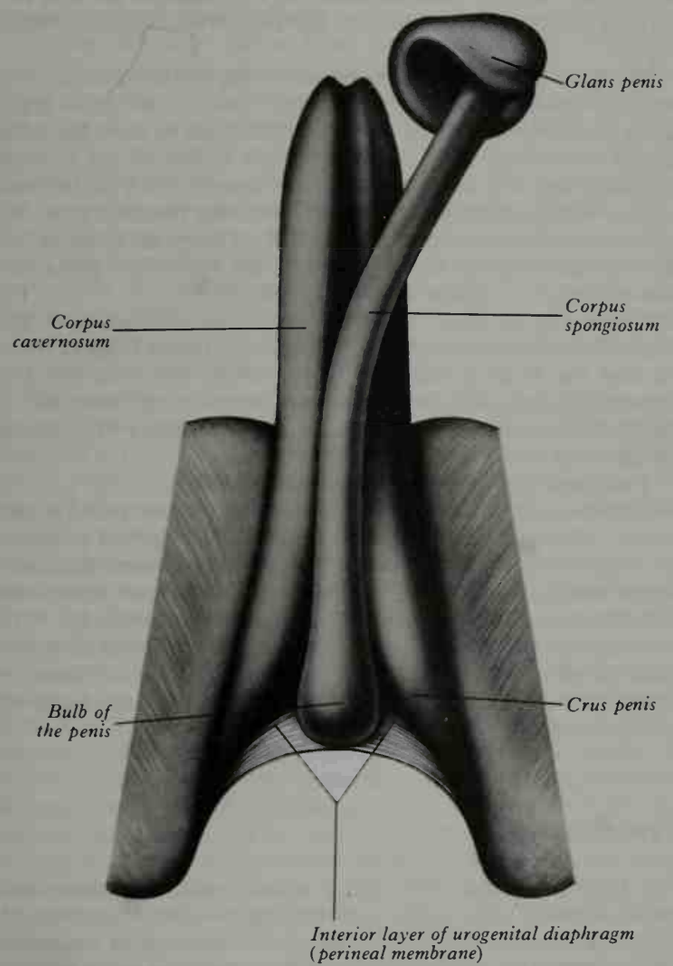
The *testicular veins* are described on p. 762.

The *lymph vessels* of the testis are described on p. 797.

The *nerves* are the genital branch of the genitofemoral nerve (p. 1107), the cremasteric nerve and the testicular plexus of the sympathetic (p. 1134), joined by filaments from the pelvic plexus which accompany the deferential artery.

The Scrotum

The *scrotum* is a cutaneous and fibromuscular sac containing the testes and the lower parts of the spermatic cords, and dependent below the pubic symphysis in front of the upper parts of the thighs. It is divided on its surface into right and left halves by a cutaneous ridge, or *raphe*, which is continued ventrally to the inferior surface of the penis, and dorsally along the middle line of the perineum to the anus; the left usually descends a little more than the right, in correspondence with the greater length of the left spermatic cord. The raphe indicates the bilateral origin of the scrotum from the genital swellings (p. 220). The external appearance varies in different circumstances: thus, under the influence of warmth, and in old and debilitated persons, the scrotum is smooth, elongated and flaccid; but, under the influence of cold, and in the young and robust, it is short, corrugated, and closely applied to the testes. It consists of the skin and the dartos muscle, together with the external spermatic, cremasteric and internal spermatic fasciae, already described in connexion with the spermatic cord. The inner surface of the internal spermatic fascia is loosely attached to the parietal layer of the tunica vaginalis (**8**.171).



The *scrotal skin* is very thin, of a brownish colour, and often thrown into folds or rugae. It is beset with thinly scattered, crisp hairs, the roots of which are visible through the skin; it is provided with sebaceous glands, the secretion of which has a peculiar odour. It also contains numerous sweat glands, pigment cells, and nerve endings responding to mechanical stimulation of the hairs and skin, and to variations in the circumambient temperature. Subcutaneous adipose tissue is lacking.

The *dartos muscle* is a thin layer of nonstriated muscular fibres, continuous around the base of the scrotum with the superficial fascia of the groin and of the perineum. It sends inwards a sagittal *septum of the scrotum*, which connects the raphe to the inferior surface of the radix of the penis, and divides the scrotum into two cavities for the testes. The scrotal septum is composed of all the layers of the scrotal wall, except the skin, which forms one continuous investment to the entire scrotum. The dartos muscle is closely united to the skin, but is connected with the subjacent parts by delicate areolar tissue, by means of which it is able to move with great independence. However, Shafik (1977) has described a fibromuscular band, which he calls the '*scrotal ligament*', extending from the dartos sheet to the inferior pole of the testis. He regards this as part of the thermoregulatory mechanism (p. 1415).

Vessels and Nerves

The *arteries* supplying the scrotum are the external pudendal branches of the femoral artery (p. 726), the scrotal branches of the

internal pudental artery (p. 722), and the cremasteric branch from the inferior epigastric artery (p. 724). The subcutaneous plexuses of the scrotal vessels are dense and carry a substantial blood flow to effect loss of heat (Esser 1932). Arteriovenous anastomoses of a simple but large-calibre type are prominent (Molyneux 1965). (See also a short discussion on temperature regulation of the testis on p. 1415.) The *veins* follow the course of the corresponding arteries. The *lymph vessels* end in the inguinal lymph nodes (p. 791). The *nerves* are the ilio-inguinal and genital branch of the genitofemoral (p. 1107), the two posterior scrotal branches of the perineal nerve (p. 1116), and the perineal branch of the posterior

8.172 Ventral aspect of the constituent erectile masses of the penis in erect position. The glans penis and the distal part of the corpus spongiosum are shown detached from the corpora cavernosa penis and turned to the left.

femoral cutaneous nerve (p. 1111). It is to be noted that the anterior third of the scrotum is supplied mainly from the first lumbar segment of the spinal cord (through the ilio-inguinal and genitofemoral nerves), whereas the posterior two-thirds are supplied mainly from the third sacral segment (through the perineal and posterior femoral cutaneous nerves). The ventral axial line of the lower limb (p. 1117) passes between these two differently innervated parts of the scrotum. A spinal anesthetic consequently needs to be injected much higher up to anaesthetize the anterior rather than the posterior part of the scrotum.

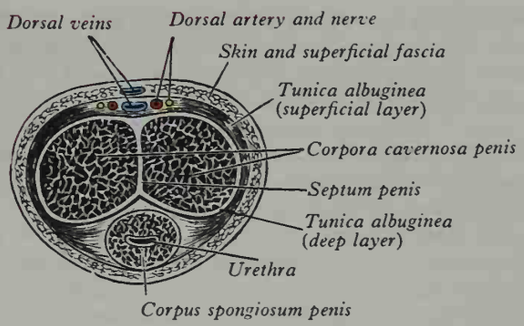
The Penis

The penis is the male organ of copulation. It comprises an attached portion, termed the *radix* or *root*, which is situated in the perineum, and a free, normally pendulous part, termed the *corpus* or *body*, which is completely enveloped in skin.

The radix of the penis comprises the three masses of erectile tissue which lie in the urogenital triangle of the perineum. They include the two crura and the bulb of the penis, which are firmly attached to the margins of the pubic arch and the perineal membrane respectively. The crura and bulb of the penis are, in fact, no more than the posterior regions of the corpora cavernosa and the corpus spongiosum; and the junctions between the former (in the radix penis) and the latter (in the 'free' corpus penis) are imperceptible and impossible of exact definition.

The *crus penis* (**8**.172) commences posteriorly as a blunt, rounded process, which is attached to bone immediately anterior to the ischial tuberosity. It is an elongated structure, closely applied and firmly adherent to the everted border of the conjoined pubic and ischial rami, and covered by the ischiocavernosus (p. 563). Anteriorly it converges towards its fellow and the median plane, presenting a slight enlargement just posterior to this point. Near the inferior border of the pubic symphysis the two crura bend sharply downwards and forwards to become continuous with the corpora cavernosa of the body of the penis.

The *bulb of the penis* (**8**.159, 172) occupies the space between the two crura and is firmly connected to the inferior aspect of the fascia forming the perineal membrane, from which it receives a fibrous investment. Oval in section, it narrows anteriorly to become continuous with the corpus spongiosum of the body of the penis, bending sharply downwards and forwards as it does so. Its convex superficial surface is completely overlapped by the bulbospongiosus; its flattened deep surface is pierced above its centre by the urethra, which traverses its substance to reach the corpus spongiosum. It is this part of the urethra which exhibits the intrabulbar fossa (p. 1408).



The corpus of the penis is composed of three elongated masses of erectile tissue which are capable of considerable enlargement when they are engorged with blood during erection of the organ. When flaccid, the body of the penis is cylindrical, but when erect, it approaches the form of a triangular prism with rounded angles. The surface which is posterosuperior during erection is spoken of as the *dorsum* of the penis, and the opposite aspect is the *urethral surface*. The masses of erectile tissue are termed the right and left corpora cavernosa and the corpus spongiosum penis, and it is to be emphasized again that they are the continuations of the crura and bulbus penis.

The *corpora cavernosa penis* form the greater part of the substance of the body of the penis. Throughout their length they are in close apposition with each other, being surrounded by a common fibrous envelope and separated only by a median fibrous septum. On the urethral surface the combined mass shows a wide median groove, adjoining the corpus spongiosum (**8**.173), and on the dorsal surface, a similar but narrower groove contains the deep dorsal vein of the penis. The two corpora cavernosa do not reach the end of the penis but terminate, within the hollow internal (proximal) aspect of the glans penis, in a rounded conical extremity, on which each forms a small projection (**8**.172). Proximally, each is continuous with the corresponding crus penis.

The corpora cavernosa penis are surrounded by a strong, fibrous envelope (tunica albuginea) consisting of superficial and deep strata. The superficial fibres are longitudinal, and form a single tube which encloses both corpora; the deep fibres are arranged circularly and surround each corpus separately, and form by their junction in the median plane the *septum of the penis*. This septum is thick and complete proximally, but imperfect in the more distal region of the penis, where it consists of a series of bands arranged like the teeth of a comb; it is therefore sometimes named the *pectiniform septum*.

The *corpus spongiosum penis*, which is traversed throughout its whole length by the spongiose part of the urethra, lies in the median groove on the urethral surface of the conjoined corpora cavernosa. It is cylindrical and tapers slightly towards its distal end. It is surrounded by a fibrous sheath (tunica albuginea). Near the extremity of the penis it suddenly expands to form a somewhat conical enlargement, more aptly described as being like an acorn, whence its name, the glans penis (**8**.172); traced towards the perineum, it becomes the bulbus penis.

The *glans penis* projects dorsally over the free extremities of the corpora cavernosa, presenting a shallow concave surface to which they are attached. The base of the glans has a projecting margin,

8.173 A transverse section of human penis.

the *corona glandis*, which overhangs an obliquely grooved constriction, the *neck of the penis*. The navicular fossa (p. 1408) of the urethra lies within the glans and opens by a sagittal slit on or near its apex.

The skin covering the penis is remarkable for its thinness, its dark colour and its looseness of connexion with the fascial sheath of the organ. At the neck of the penis it is folded upon itself to form the *prepuce* or *foreskin*, which overlaps the glans for a variable distance. The internal layer of the prepuce is confluent along the line of the neck with the thin skin which covers and adheres firmly to the glans and is continuous with the mucous membrane of the urethra at the external urethral orifice. On the urethral surface of the glans penis a small median fold passes from the deep surface of the prepuce to a point on the glans immediately proximal to the external urethral orifice; this is the *frenulum* of the prepuce. The high degree of cutaneous sensitivity possessed by the general surface of the glans penis is even more marked near the frenulum. The prepuce is separated from the glans penis by a potential space or cleft—the *preputial sac*—which presents two shallow fossae, one on each side of the frenulum. On the corona of the glans and on the neck of the penis there are numerous small *preputial glands*; these secrete a sebaceous material, the *smegma*.

The *superficial fascia of the penis* is devoid of fat and consists of very loosely arranged areolar tissue, into which a few fibres of the dartos muscle extend from the scrotum (p. 1418). As in the suprapubic region of the abdominal wall, the deepest layer is somewhat condensed; it forms the *fascia penis*, which surrounds both the corpora cavernosa and the corpus spongiosum and separates the superficial from the deep dorsal vein. It does not extend beyond the neck of the penis, where it blends with the fibrous envelopes of the corpora cavernosa and corpus spongiosum. Proximally, it is continuous with the dartos muscle and the fascia covering the urogenital region of the perineum (p. 1418).

The weight of the body of the penis is supported by two ligaments, both continuous with the fascia of the penis and consisting very largely of elastin fibres. The *fundiform ligament* (**5**.45) springs from the lower part of the linea alba and splits into two lamellae which pass one on each side of the penis and unite below with the septum of the scrotum. The *suspensory ligament* is inferior or deep to the fundiform ligament. It is triangular in shape and is attached, above, to the front of the pubic symphysis. Below, it blends with the fascia penis on each side of the organ.

Structure of the penis. From the internal surface of the fibrous envelope of the corpora cavernosa penis, as well as from the sides of the septum, numerous *trabeculae* arise, and cross the corpora cavernosa in all directions, thus dividing them into a number of *cavernous spaces*, and giving the entire structure a spongy form (**8**.173). These trabeculae are composed of white fibrous tissue, elastin fibres and nonstriated muscular fibres, and they contain numerous arteries and nerves. The cavernous spaces are filled with blood during erection, but many are empty in the flaccid penis. They are lined with a continuous layer of flattened endothelial cells without fenestrae (Leeson and Leeson 1965).

The fibrous envelope (tunica albuginea) of the corpus spongiosum penis is thinner, whiter in colour, and more elastic than that of the corpora cavernosa penis. It is formed partly of nonstriated muscular fibres, and a layer of the same tissue surrounds the epithelium of the urethra (p. 1408).

Vessels and Nerves

The *arteries* bringing the blood to the cavernous spaces are the deep arteries of the penis (p. 722), and branches from the dorsal arteries of the penis, which perforate the fibrous capsule along the upper surface, especially near the extremity of the organ. On entering the cavernous structure the arteries divide into branches which are supported and enclosed by the trabeculae. Some of these arteries end in a capillary network, which opens directly into the cavernous spaces; others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, named *helicine arteries*. They open into the cavernous spaces, and from them small capillary branches go to supply the trabecular structure. They are most abundant in the posterior parts of the corpora cavernosa. For a detailed description *see* Alvarez-Morujo (1968).

The *veins* drain blood from the cavernous spaces by means of a series of vessels, some of which emerge from the base of the glans penis and converge on the dorsum of the penis to form the deep dorsal vein; others pass out on the upper surface of the corpora cavernosa and join the same vein; some emerge from the inferior surface of the corpora cavernosa and, receiving branches from the corpus spongiosum, wind round the side of the penis to end in the deep dorsal vein; but many pass out at the root of the penis and join the prostatic plexus. (See also p. 761.)

Erection of the penis is a purely vascular phenomenon, independent of muscular compression exerted by the ischiocavernosi and the bulbospongiosus. Rapid inflow from the helicine arteries fills the cavernous spaces and the resulting distension of the corpora cavernosa acts as a contributory factory by pressing on the veins which drain the erectile tissue.

The *lymph vessels* are described on p. 797.

The *nerves* are from the second, third and fourth sacral spinal nerves, through the pudendal nerve and the pelvic plexuses (p. 1115). On the glans and on the bulb of the penis some filaments of the cutaneous nerves have lamellated corpuscles connected with them, and many of them end in peculiar end bulbs (p. 853). Stimulation of the cutaneous receptors of the glans and frenulum of the penis is, of course, of great importance in the maintenance of the erect condition of the penis and in the initiation of orgasm and ejaculation of semen.

The Prostate

The prostate (**8**.164, 169, 170) is a firm, partly glandular and partly fibromuscular body, surrounding the commencement of the urethra in the male. It is situated at a low level in the lesser pelvis, behind the inferior border of the symphysis pubis and the pubic arch, and anterior to the ampulla of the rectum, through the wall of which it may be palpated. It is somewhat conical in shape, and thus presents for examination a base or vesical aspect, an apex, posterior, anterior and two inferolateral surfaces.

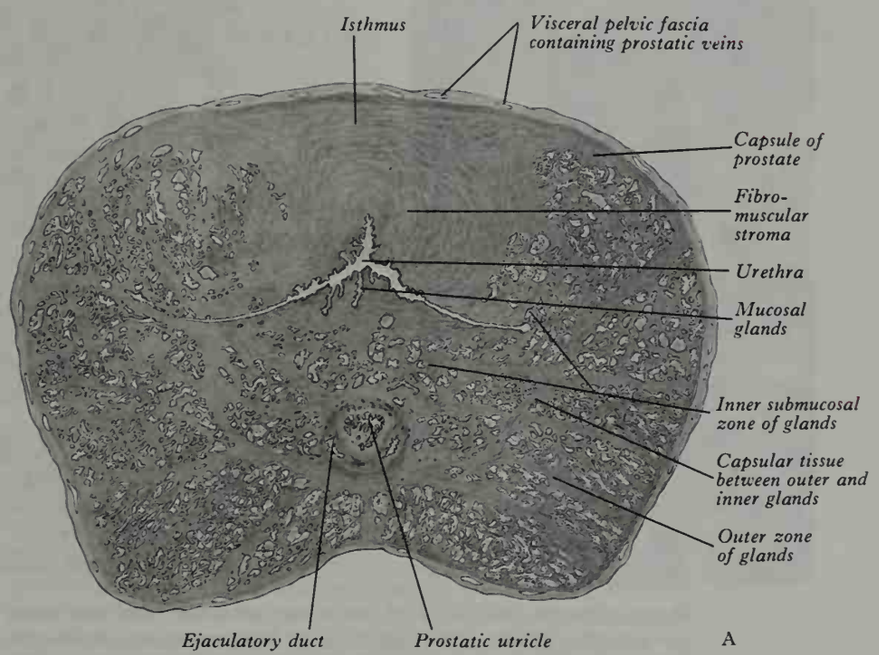
The *base* is for the greater part of its extent directly contiguous with the neck of the urinary bladder superior to it: the urethra enters this surface nearer to its anterior border.

The *apex* is inferior and is in contact with the fascia on the superior aspects of the sphincter urethrae and the transversus perinei profundus (p. 536).

The *posterior surface* is transversely flat and vertically convex; it is separated from the rectum by the prostatic sheath and loose connective tissue external to the sheath. Near to its superior (juxtavesical) border is a depression where the two ejaculatory ducts penetrate the prostate, dividing this surface into a superior and an inferior, larger, part. The superior part is variable in size; it is usually regarded as the external aspect of the *median lobe*. The inferior area displays a shallow, median sulcus, which is usually considered to mark a partial separation of *right and left lateral lobes*, which account for the main mass of the prostate and are really continuous posterior to the urethra. A band of fibromuscular tissue, ventral to the urethra, joins the lateral lobes together, and is often referred to as the anterior lobe. This contains fewer glandular structures than are found in the rest of the gland. This simplified view of the lobation of the prostate gland, based

primarily upon the classical study of Lowsley (1912) is presented here, despite the large number of modifications introduced by subsequent observers, among whom there persist confusions and inconsistencies which have not yet been completely resolved. Some investigators deny the existence of lobes which can be distinguished by dissection; and those who favour lobation differ among themselves in their boundaries and terminology. McNeal (1975) has analysed these disagreements. Lobation has assumed an importance through the conviction among some investigators that malignant tumours are derived from particular regions of the prostate. This pathological and surgical interest prompted the study of Tisell and Salander (1975), who claim to have confirmed a recognizable lobar structure (by dissection of more than 100 human prostate glands). From their extensive observations they recognize two large *lateral lobes*, but they consider that these do not form any part of the dorsal (rectal) aspect of the prostate. They describe this dorsal region as paired *dorsal lobes*, which extend to the lateral aspects of the gland and also form all of its apex. They recognize *median lobes*, but define these as deeply placed in the prostate, extending around the urethra (except at the apex of the prostate) deep to the dorsal and lateral lobes, thus forming a deeper layer, as if patterned like an onion. Their median lobes may be equated with the *internal zone* described below. All three pairs of lobes are, they affirm, separable by dissection. At present it is difficult to reconcile the differences between this and other descriptions of prostatic lobation, and the question must be left *sub judice*. (*See*, however, Goland 1975.)

The *anterior surface* is transversely narrow and convex, and extends from apex to base. It lies about 2 cm behind the pubic symphysis, separated by a plexus of veins and some loose adipose tissue. Near its superior limit it is connected to the pubic bones by the puboprostatic ligaments. The urethra emerges from this surface a little anterosuperior to the apex of the prostate.



The *inferolateral surfaces* are prominent, and are related to the anterior parts of the levatores ani, which are, however, separated from the gland by a plexus of veins embedded in fibrous tissue which forms the lateral part of the sheath of the organ.

The prostate measures about 4 cm transversely at the base, about 2 cm in its anteroposterior, and 3 cm in its vertical diameters. Its weight is about 8 gm. It has a fibrous sheath, partly vascular and partly avascular. On each side the sheath consists of fibrous tissue in which are embedded the veins of the prostatic venous plexus (**6**.138). Anteriorly, it is continuous with the puboprostatic ligaments (p. 1405) and, inferiorly, it blends with the fascia on the deep surfaces of the sphincter urethrae and each transversus perinei profundus, and with the perineal body (**5**.56). The posterior wall of the sheath has a different constitution and is avascular. In the male fetus, at the fourth month, the rectovesical peritoneal pouch extends downwards to the pelvic floor and separates the prostate from the rectum. The lower part of this recess becomes obliterated and the fused peritoneal layers form the posterior wall of the prostatic sheath (Smith 1908). This fibrous layer has been termed the *rectovesical fascia*. Traces of its origin from two separate layers are evident, for there exists a central plane of cleavage. Above, it extends upwards over the posterior aspects of the seminal vesicles and the deferent ducts and is connected to the peritoneal floor of the rectovesical pouch (**5**.54). On each side, it is connected with the posterior ligament of the bladder (p. 1406) and, below, where it becomes closely adherent to the prostate, it merges into the perineal body. Others have denied such peritoneal fusion and maintain that the rectovesical fascia is formed simply by condensation of loose areolar tissue (Silver 1956). The anterior portions of the levatores ani pass posteriorly from the pubis and embrace the sides of the prostate; from the support thus afforded to the organs these parts of the muscles are named the *levatores prostatae*.

The prostate is traversed by the urethra and the ejaculatory ducts and contains the prostatic utricle. The urethra usually lies along the junction of its anterior with its middle one-third. The ejaculatory ducts pass obliquely antero-inferiorly through the posterior part of the prostate, and open into the prostatic region of the urethra (p. 1408).

Structure (**8**.174, 175). The prostate gland varies in colour from grey through pale pink to reddish according to its activity, and is of great density. It is enveloped in a thin but firm fibrous capsule, distinct from the sheath derived from the pelvic fascia, the latter containing a plexus of veins. The capsule is firmly adherent to the prostate and is structurally continuous with a median septum in the urethral crest which separates the lateral masses below the level of the colliculus seminalis. The capsule is also continuous with numerous fibromuscular septa which enmesh the glandular tissue.

The *muscular tissue* is mainly nonstriated (Hutch and Rambo 1970); ventral to the urethral lumen is a distinct layer of nonstriated muscle which curves to merge with the great mass of such muscle found in the fibromuscular septa of the gland. Superiorly the former is continuous with the nonstriated muscle of the bladder. However, a striated muscle, crescentic in sections transverse to the urethra, is present anterior to the nonstriated muscle ventral to the urethral lumen, and is continuous inferiorly with the sphincter urethrae in the deep perineal pouch. Its fibres lie transversely internal to the fibrous capsule, into which they are inserted laterally by diffuse collagen bundles; other collagen bundles pass posteromedially through the gland, merging with its

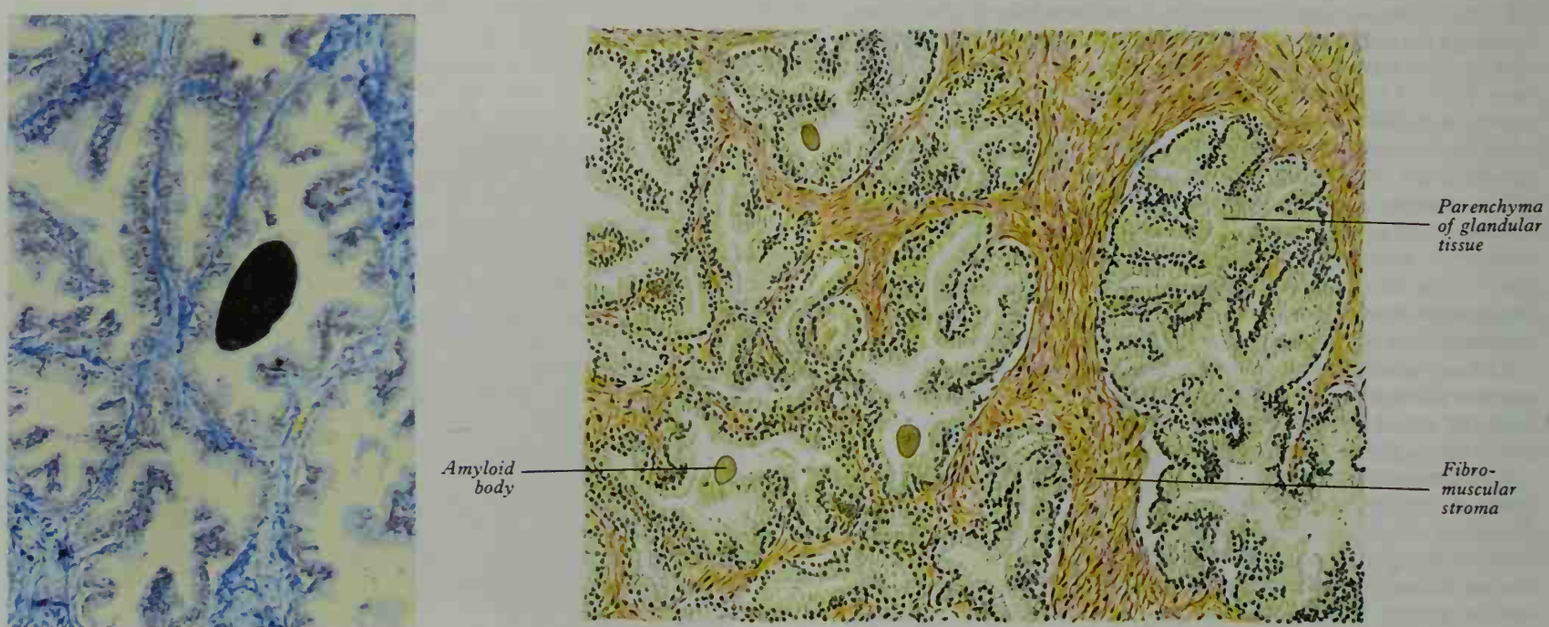
8.174A and B Human prostate. A Transverse section at a level to show the prostatic utricle and ejaculatory ducts. B Transverse section to show the urethral crest (stained by haematoxylin and eosin and kindly lent by Dr. L. M. Franks, Imperial Cancer Research Institute, London). Compare with A, and see text for further details. Both A and B are slightly more than twice natural size. Ventral is to the top in both figures.

fibromuscular septa and the septum of the urethral crest. This muscle, supplied by the pudendal nerve, is generally held to be a compressor urethrae (Haines 1969). From the above description however, it is suggested by Brookes (personal communication) that it is possibly a 'dilator' urethrae, pulling the urethral crest backwards and the prostatic sinuses forwards. Simultaneously, the glands are compressed and their contents expelled into the urethral lumen, now expanded into a reservoir adequate to contain the seminal fluid (3–5 ml) during the variable period of sexual excitement prior to ejaculation.

The *glandular substance* is composed of numerous follicles with frequent internal papillary elevations. The follicles open into elongated canals which join to form from twelve to twenty small excretory ducts. They are connected together by areolar tissue, supported by prolongations from the fibrous capsule and muscular stroma, and enclosed in a delicate capillary plexus. The epithelium which lines the canals and the follicles is of the columnar variety. Electron microscopic studies reveal microvilli at the luminal surfaces of the cells. There are relatively few short lengths of granular endoplasmic reticulum and some free ribosomes in the cytoplasm. Ultramicroscopic vesicles, the contents of some of which give a positive reaction for acid phosphatase, are also present. The apposed borders of the cells are mainly straight and the plasma membranes are united by desmosomes (Fisher and Jeffrey 1965). The *prostatic ducts* open mainly into the prostatic sinuses in the floor of the prostatic part of the urethra, and have a bilaminar epithelium, the luminal layer consisting of columnar and the external of small cubical cells. Small colloid masses, known as *amyloid bodies*, are often found in the glandular tubes. The prostatic secretion and the secretion of the seminal vesicle together form the bulk of the seminal fluid. The prostatic secretion is slightly acid and contains acid phosphatase and fibrinolysin.

Histological sections of the prostate (**8**.174) do not show a lobar pattern, but two well-defined, concentric zones of glandular tissue, partially surrounding the prostatic urethra, are recognizable (Le Duc 1939; Franks 1954, Fergusson and Gibson 1956). The larger, *peripheral zone* is composed of long, branched glands, the ducts of which curve posteriorly to open mainly into the prostatic sinuses, though some open into the lateral walls of the urethra. The *internal zone* consists of a set of 'submucosal' glands, the ducts of which open into the floor of the prostatic sinuses, and partly on the colliculus seminalis, and an *innermost* group of short, simple 'mucosal' glands, which surround the upper part of the prostatic urethra. Anteriorly, in the isthmus of the prostate, the peripheral zone and the 'submucosal' glands are deficient. The peripheral and internal zones are separated by an ill-defined, irregular 'capsule'. Carcinoma affects almost exclusively the former zone, while the internal zone is particularly prone to benign hypertrophy (hyperplasia); this latter growth projects into the bladder and displaces the peripheral zone postero-inferiorly, producing thereby a more distinct 'capsule' between the outer and inner zones, which provides a 'cleavage plane' during surgical enucleation of the hypertrophic growth.

Vessels and nerves. The *arteries* (Clegg 1955, 1956) supplying the prostate are derived from the internal pudendal, inferior vesical and middle rectal arteries. Its *veins* form a plexus around the sides and base of the gland (p. 761); they receive in front the deep dorsal vein of the penis, and end in the internal iliac veins. The *lymph vessels* are described on p. 797. The *nerves* are derived from the inferior hypogastric (pelvic) plexus (p. 1135).



Age Changes in the Prostate

At birth (Swyer 1944) the prostate consists of a duct system embedded in a stroma which forms a large part of the bulk of the gland. Follicles are represented by small end buds on the ducts. There is a hyperplasia and squamous metaplasia of the epithelium of the ducts, the colliculus seminalis, and the prostatic utricle which are possibly due to the action of maternal oestrogens circulating in the fetal blood. These changes subside in about six or seven weeks and then the prostate undergoes little structural change until about the ninth year, when there occurs a hyperplasia of the duct epithelium and the formation of side buds leading to an elaboration of the duct system. During the period up to puberty there is a slow and continuous increase in the size of the prostate.

At puberty changes occur very rapidly over a period of about six months to one year. There is rapid increase to more than twice the size of the pre-pubertal gland, due almost entirely to the development of follicles, partly from the end buds on the ducts, and partly from modification of branches of the ducts. This change is associated with some condensation of the stroma, which becomes reduced in volume relative to the amount of glandular tissue. These changes are probably due to the secretion of testosterone into the bloodstream by the testis.

During the third decade the glandular epithelium is increased by irregular complication of the infolding of epithelium into the lumen of the follicles.

After the third decade the size remains fairly constant until the age of forty-five to fifty. Infoldings of the epithelium tend to disappear so that the outlines of the follicles are more regular and

8.175 Characteristic fields of the human prostate. Note the highly convoluted columnar epithelium, forming papillary projections into the lumen of a follicle, and abundant interfollicular fibromuscular tissue. (Specimen on left provided by Dr. Abla el Nasser, Department of Anatomy, Guy's Hospital Medical School, from a University of London Ph.D. Thesis entitled *The Embryology of the Prostate Gland*, 1980.)

amyloid bodies increase in number. All these changes indicate the beginning of prostatic involution.

After the age of forty-five to fifty the prostate either may undergo benign hypertrophy so that its size increases gradually until death, or it may undergo progessive atrophy.

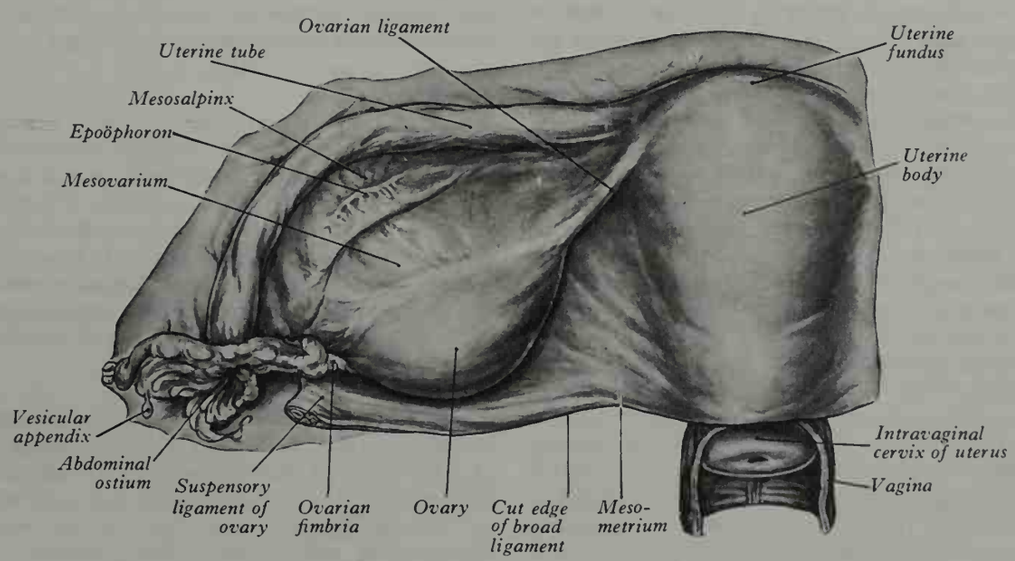
Applied Anatomy. In advanced life the prostate often becomes considerably enlarged and projects into the bladder so as to impede the passage of urine by elongating and distorting the prostatic urethra. In some cases the median lobe enlarges most, and even a small enlargement of this lobe may act injuriously, by forming a sort of valve over the internal urethral orifice, preventing the passage of urine; and the more the patient strains, the more completely will it block the opening into the urethra. The hypertrophied part of the gland projecting into the bladder may be removed by the operation of prostatectomy.

Valveless venous communications between the prostatic plexus and the extradural venous plexuses have been shown to be a normal feature, and to be probably an important factor in the metastasis of prostatic neoplasms to the vertebral bodies (Batson 1940; Franks 1953).

THE BULBO-URETHRAL GLANDS

The bulbo-urethral glands (**6**.97) are two small, round and somewhat lobulated bodies, of a yellow colour and about a centimetre in diameter. Each is placed lateral to the membranous urethra, superior to the perineal membrane. They lie above the bulb of the penis, and are enclosed by the fibres of the sphincter urethrae. They gradually diminish in size as age advances.

The excretory duct of each gland is nearly 3 cm long; it passes obliquely forwards external to the mucous membrane of the membranous part of the urethra, penetrates the inferior fascia of the urogenital diaphragm, and opens by a minute orifice on the floor of the spongiose part of the urethra about 2·5 cm below the inferior fascia of the urogenital diaphragm (perineal membrane).



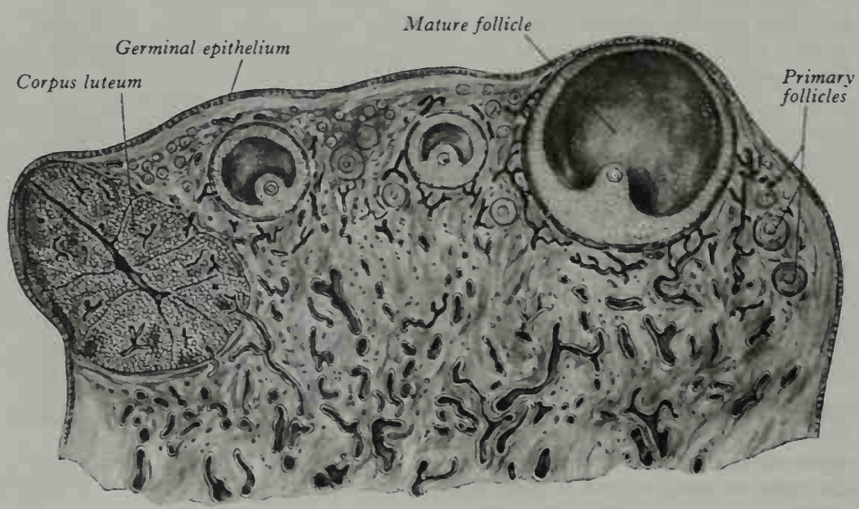
Structure. Each gland is made up of several lobules which are held together by a fibrous investment. Each lobule consists of a number of acini of columnar epithelial cells. The secretion of the bulbo-urethral glands is an additional constituent of the seminal fluid, but the glands are very small in man as compared with many animals, and the part which they play is uncertain.

REPRODUCTIVE ORGANS OF THE FEMALE

The female's reproductive system may be considered to consist of the internal and the external genitalia. The *internal organs* are situated within the lesser pelvis, and are the ovaries, the uterine tubes, the uterus and the vagina. The *external organs* are antero-inferior to the pubic arch and they include the mons pubis, the labia majora et minora pudendi, the clitoris, the bulb of the vestibule, the greater vestibular glands, and the vestibule itself.

The Ovaries

The ovaries (**8**.176, 183) are homologous with the testes in the male, developing also from the genital ridge (p. 217). They are situated one on each side of the uterus close to the lateral wall of the lesser pelvis, and attached to the posterosuperior aspect of the broad ligament of the uterus, postero-inferior to the uterine tube (**8**.176). They are of a greyish-pink colour, and present a smooth surface before regular ovulation begins, but thereafter the surface is distorted by the cicatrization which follows degeneration of successive corpora lutea. Each ovary is almond-shaped (amygdaloid) and is about 3 cm long, 1·5 cm wide, and about 1 cm thick. The position of the ovary is subject to a wide range of variation in women who have borne children, because it is displaced in the first pregnancy and probably never returns to its original location. It is also variably mobile and may change its position to some degree, according to the state of surrounding organs, such as the intestines. The description given here applies to that of the nulliparous woman. In the upright position the long axis of the ovary is vertical; the gonad presents lateral and medial surfaces, tubal and uterine extremities, and mesovarian and free borders. The ovary occupies a depression, the *ovarian fossa*, on the lateral pelvic wall; this fossa is bounded anteriorly by the obliterated umbilical artery, and posteriorly are the ureter and the internal iliac artery. The *tubal* (superior) *extremity* is near the external iliac vein; to it are attached the ovarian fimbria of the uterine tube and a fold of peritoneum, the *suspensory ligament of the ovary*, which contains the ovarian vessels and nerves, and passes superiorly over the external iliac vessels (**8**.183) to become continuous with the peritoneum on the psoas major, posterior to the caecum or descending colon. The *uterine* (inferior) *extremity* is directed downwards towards the pelvic floor; it is usually narrower than the tubal extremity, and is attached to the lateral angle of the uterus, postero-inferior to the uterine tube, by a rounded cord termed the *ligament of the ovary*, which lies within the broad



8.176 Posterosuperior aspect of the uterus and the left broad ligament. The 'ligament' has been spread out and the ovary is displaced downwards.

ligament and contains some nonstriated muscular fibres. The *lateral surface* is in contact with the parietal peritoneum which lines the ovarian fossa; it separates the ovary from the extraperitoneal tissue and the obturator vessels and nerve. The *medial surface* is to a large extent covered by the uterine tube, and the peritoneal recess between this aspect of the gland and the mesosalpinx which overlaps it is usually termed the *ovarian bursa*. The *mesovarian border* is straight and is directed towards the obliterated umbilical artery; it is attached to the back of the broad ligament by a short fold named the *mesovarium*. Between the two layers of this fold the blood vessels and nerves pass to the hilum of the ovary. The *free border* is convex, and is directed towards the ureter. The uterine tube arches over the ovary, running upwards in relation to its mesovarian border, curving over its tubal extremity, and then passing downwards on its free border and medial surface (**8**.183).

In embryonic and early fetal life the ovaries are situated, like the testes, in the lumbar region near the kidneys, but they gradually descend into the lesser pelvis (p. 385). Accessory ovaries may occur, either in the mesovarium or in the adjacent part of the broad ligament.

Structure of the Ovary

The surface of the ovary is covered, in the young female, with a layer of cuboidal cells which become flattened later in life. This so-

8.177 Semi-diagrammatic section of an ovary.

called *germinal epithelium* gives to the ovary a dull grey colour as compared with the shining smoothness of the peritoneum; the transition between the flattened mesothelium of the peritoneum and the cuboidal cells covering the ovary is usually marked by a fine white line around the anterior, or mesovarian, border of the ovary.

The ovary, after puberty, has a thick cortex which contains the ovarian follicles and corpora lutea and surrounds, except at the hilum, a richly vascular medulla. The interstitial framework or *stroma* of the *cortex* is of a dense texture and consists of networks of reticular fibres and numerous fusiform cells, which resemble nonstriated muscle cells, though they contain no fibrils and are possibly mesenchymal elements. These stromal cells contribute to the growth of the theca folliculi (*vide infra*), and they may secrete oestrogens. The stroma of the *medulla* is of a looser texture and consists of connective tissue, with many elastin fibres, nonstriated muscle cells and numerous large blood vessels, particularly veins. At the hilum, strands of nonstriated muscle cells enter the medulla from the mesovarium. The cortex is much less vascular than the medulla. Immediately beneath the germinal epithelium, the connective tissue of the cortex is condensed to form a delicate *tunica albuginea*—which increases in density with advancing years. It is a collagenous layer, in contradistinction to the general stroma of the ovary. During prenatal life the stroma of the cortex contains small groups of *interstitial cells*, but after puberty these cells are only present in the thecae of atretic ovarian follicles.

Ovarian follicles

At birth, the cortex of the ovary contains very numerous *primary ovarian follicles*. Each of these consists of a large central cell, the *oögonium*, surrounded by a single layer of small cuboidal or flattened elements, the *follicular cells*. The prenatal development of these follicles is described in the Embryology Section (p. 217). Many of them degenerate both during childhood and after puberty. After puberty some develop each month to form *vesicular ovarian (Graafian) follicles*, one of which usually matures and ruptures (ovulation). After puberty, and during the 'child-bearing period' of life (that is, up to the time of the menopause), the cortex contains ovarian follicles, corpora lutea in all stages of development, and atretic follicles (**8**.177).

The primary follicle develops into a vesicular follicle in the following manner. The follicular cells multiply and become many layered; a cavity (the *antrum folliculi*) containing fluid (the *liquor folliculi*) appears between the cells and separates them into two collections. The outer set forms the *membrana granulosa* and the inner set, which surrounds the ovum and attaches it to one pole of the follicle, forms the *cumulus ovaricus* (**8**.178). The stromal cells of the cortex of the ovary form a sheath (the *theca folliculi*) around the follicle and this sheath is differentiated into an inner part, the *tunica interna*, which is cellular in character and permeated by a capillary plexus, and an outer part, the *tunica externa*, which is fibrous in character. The tunica interna is separated from the membrana granulosa by a delicate basement membrane, and as the follicle is approaching its full development, the tunica interna becomes well defined and constitutes the '*thecal gland*'. The cells of the tunica interna and those of the membrana granulosa produce oestrogenic hormones (principally oestradiol), and the development of the follicle itself is stimulated by the gonadotropic hormone of the hypophysis cerebri (follicle stimulating hormone: FSH). Meanwhile the oögonium in the primary follicle transforms into a *primary oöcyte*, and the latter divides into a *secondary oöcyte* and a first polar cell. When the fully developed vesicular ovarian follicle ruptures (ovulation), it is the secondary oöcyte which is extruded, and the second polar cell is not formed unless fertilization takes place. During this maturation process the ovum also grows in size, from about 30 μm in the primordial follicle to 110 μm in the fully developed vesicular follicle. Much of this is due to the accumulation of substances to form the *yolk* or *deutoplasm*.

A fully developed follicle is 10 mm or more in diameter. As a rule, only one follicle matures and ruptures in each monthly cycle; *anovulatory* cycles may occur. However, several other primary follicles also develop to varying extents to form small vesicular follicles; but these degenerate into atretic follicles, and the cells of their tunicae internae become the interstitial cells of the ovary, which resemble those of the testis (p. 1415).

Ovulation

When the fully ripened vesicular follicle ruptures on the surface of the ovary, the secondary oöcyte, surrounded by follicular cells of the cumulus ovaricus, is normally expelled and passes into the uterine tube along its fimbriated end. If fertilization follows, it normally happens in the lateral third of the uterine tube. If fertilization does not occur, the oöcyte begins to degenerate after a short time (24–48 hours). Ovulation most frequently occurs 12–16 days before the anticipated onset of the next menstrual cycle, though it may occur outside these limits.

Corpus luteum

After ovulation, the wall of the vesicular ovarian follicle collapses and becomes folded, the cells of the membrana granulosa become greatly increased in size and a yellowish carotenoid pigment (lutein) is formed in their cytoplasm. These cells are called *luteal cells* and they form the major part of the *corpus luteum* (**8**.177). Some smaller cells (*paraluteal cells*), derived from the cells of the tunica interna, also lie on and between the superficial luteal cells. The basement membrane external to the granulosa cells vanishes,

and capillaries grow in from the vessels in the tunica interna and lie between the luteal cells. A little blood clot occupies the interior of the corpus luteum. If fertilization does not occur, the corpus luteum has a functional life of about 12–14 days, after which it shows progressive degenerative changes. Such a corpus luteum is known as a *corpus luteum of menstruation*. The degenerative changes include fatty degeneration of the luteal cells and their gradual replacement by fibrous tissue so that eventually, after a period of about two months, only a small fibrous cicatrix remains (*corpus albicans*). The synergic activities of the hypophysial gonadotropic hormones—follicle stimulating hormone (FSH), luteinizing hormone (LH) and luteotropic hormone (LTH, prolactin, or lactogen)—are responsible for the conversion of the granulosal into luteal cells. The luteal cells produce the hormone progesterone, and both the luteal and paraluteal cells produce some oestradiol. The action of these ovarian hormones (progesterone and oestradiol) on the endometrium of the uterus is described in the Embryology Section (pp. 126–129).

If pregnancy occurs, implantation of the blastocyst in the uterine endometrium normally begins on the seventh day following fertilization, and the trophoblast produces hormones (follicle stimulating hormone, luteinizing hormone, progesterone and oestradiol). These follicle-stimulating and luteinizing hormones are known as chorionic gonadotropins and they stimulate the corpus luteum of menstruation to increase in size and prolong its activity. Such a corpus luteum is known as a *corpus luteum of pregnancy*. Whereas the corpus luteum of menstruation is active for only about 12–14 days and usually is about 1 cm in diameter, the corpus luteum of pregnancy increases in size to reach about 2·5 cm in diameter about the middle of gestation and remains active until late. By the end of pregnancy it is reduced to about 1 cm in diameter and gradually, over a period of some months, undergoes the same degenerative changes as occur in the corpus luteum of menstruation.

As the female becomes older, the ovary becomes more and more fibrotic due to the formation of corpora albicantia and, after the menopause, which occurs usually near the age of fifty years, the above changes in the ovary, involving the formation of follicles and corpora lutea, come to an end.

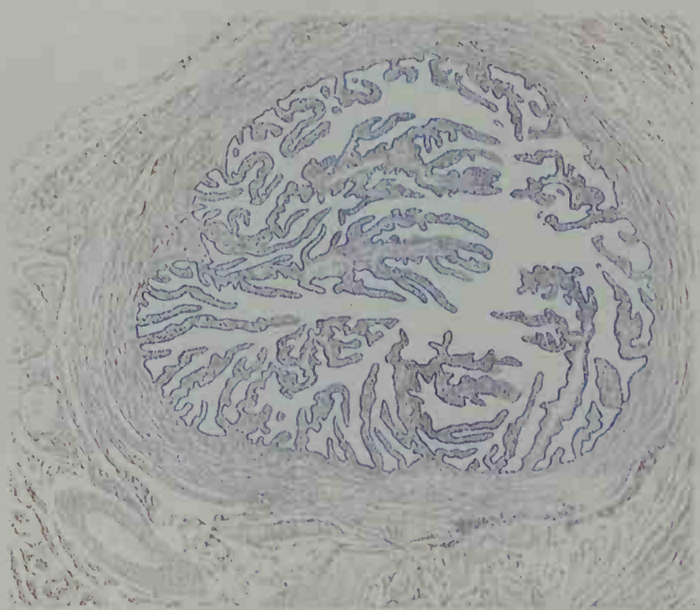
Vessels and nerves. The *arteries* of the ovaries and uterine tubes are the ovarian arteries from the abdominal aorta (p. 718). The *veins* emerge from the hilum in the form of a leash, named the *pampiniform plexus*; the ovarian vein is formed from this plexus, and leaves the lesser pelvis in company with the artery (p. 762). The *lymph vessels* are described on p. 798. The *nerves* are derived from the ovarian plexus (p. 1134). Apart from the facts that postganglionic sympathetic and parasympathetic fibres and autonomic afferent fibres innervate the ovary, little is known of their actual distribution or their function within the ovary, particularly in humans. Bulmer (1965) and Owman *et al.* (1967) have demonstrated nerve fibres in the stroma by cholinesterase and catecholamine staining techniques, amongst others. (*See* Neilson *et al.* 1970, for a review of this literature.) Balboni (1971) has described the distribution of adrenergic fibres. However, the structures innervated, apart from vessels, and the functions of such innervation remain uncertain.

Vestigial Structures

The *epoöphoron* (**8**.176) lies in the lateral part of the mesosalpinx (p. 213) between the ovary and the uterine tube, and consists of ten to fifteen short tubules, the *transverse ductules* of the epoöphoron, which converge towards the ovary and end blindly, while their other ends open into a rudimentary duct, the *longitudinal duct of the epoöphoron*, which runs medially in the broad ligament of the uterus, parallel with the lateral part of the uterine tube. Frequently, between the epoöphoron and the fimbriated end of the uterine tube, one or more small cysts are present (the *vesicular appendices*).

In a small proportion of subjects the longitudinal duct of the epoöphoron (*duct of Gartner*) can be followed alongside the uterus to near the level of the internal os. Here it pierces the muscular wall of the uterus and descends in the wall of the cervix uteri, gradually approaching the mucous membrane, without, however, quite reaching it. The duct then runs downwards in the lateral wall of the vagina and ends at, or close to, the free margin of the hymen.

The *paroöphoron* consists of a few scattered rudimentary tubules, best seen in the child, situated in the broad ligament between the epoöphoron and the uterus.



The tubules of the epoöphoron and of the paroöphoron are remnants of mesonephric tubules; the duct of the epoöphoron is a persistent portion of the mesonephric duct (p. 213).

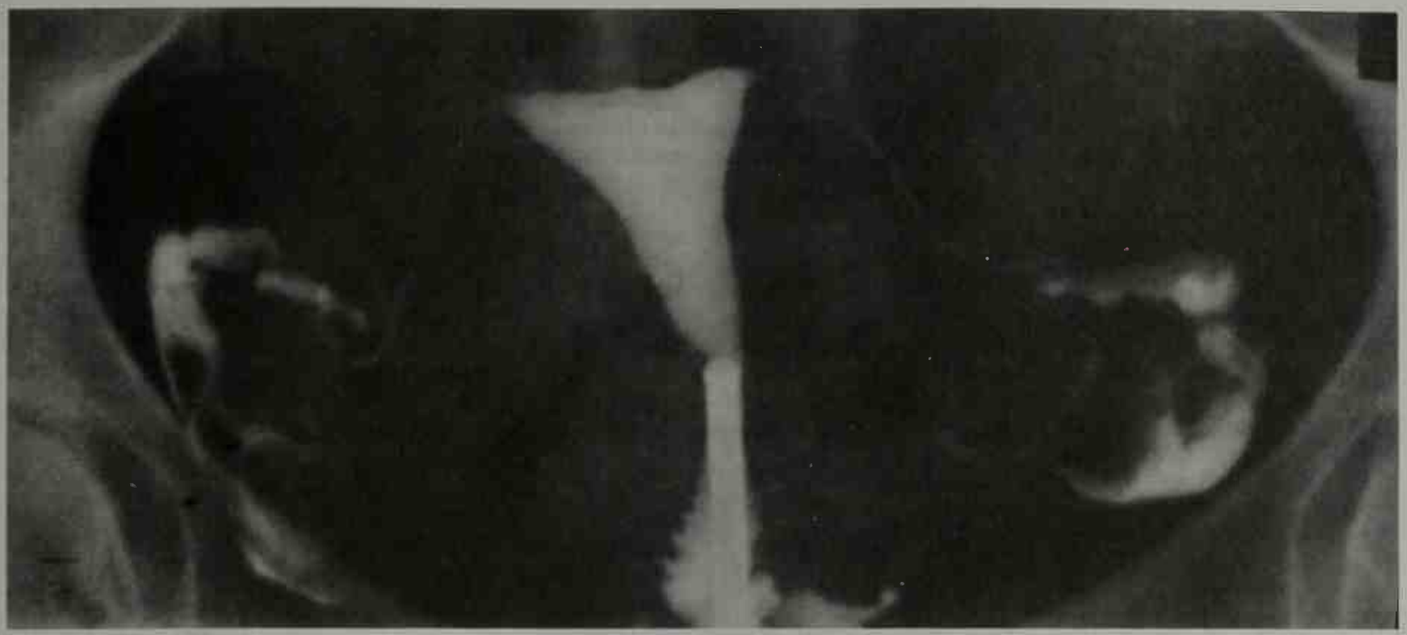
The Uterine Tubes

The two **uterine (Fallopian) tubes** (**8**.176, 182) transmit ova from the ovaries to the cavity of the uterus, and are situated in the upper margins of the broad ligaments of the uterus. Each tube is about 10 cm long, its medial end opening into the superior angle of the cavity of the uterus, the lateral end into the peritoneal cavity close to the ovary. The uterine ostium or opening is very small, and admits only a fine bristle; the opening into the peritoneal cavity is named the *abdominal ostium*, and when its muscular wall is relaxed has a diameter of about 3 mm. The abdominal opening is situated at the bottom of a trumpet-shaped expansion of the uterine tube, the *infundibulum*, the circumference of which is prolonged by a varying number of irregular processes, called *fimbriae*, and therefore this extremity of the tube is sometimes called the *fimbriated end*. The inner surfaces of the fimbriae are lined by mucous membrane, and in the larger fimbriae this exhibits longitudinal folds which are continuous with similar folds in the mucous lining of the infundibulum. One fimbria, longer and more deeply grooved than the others, is closely applied to the tubal extremity of the ovary, and is named the *ovarian fimbria*. The infundibulum opens into the *ampulla* of the tube, which is thin-walled and tortuous and forms rather more than one-half of its entire length. The ampulla is succeeded by the *isthmus*, which is round and cord-like and constitutes approximately the medial one-third. The part continued from the isthmus through the wall of the uterus is about 1 cm long, and is named the *uterine* (intramural) *part* of the tube.

8.179 Transverse section through the ampulla of a human uterine tube. Stained with haematoxylin and eosin. Magnification about × 15.



8.180 Section showing the plicated mucous membrane in the ampullary part of human uterine tube. Note the columnar epithelium. Stained with haematoxylin and eosin. Magnification about × 75.

The uterine tube extends laterally as far as the medial (uterine) pole of the ovary, and then ascends along the mesovarian border to the tubal pole, over which it arches; finally it turns downwards and ends in relation to the free border and medial surface of the ovary. In connexion with the fimbriae of the uterine tube, or with the broad ligament close to them, there are frequently one or more small pedunculated vesicles; these are termed the *vesicular appendices* (see above and **8**.176).

Structure (**8**.179, 180). The uterine tube resembles other hollow viscera in the main components of its wall, which consists of an external *serosal* layer, an intermediate stratum of *muscle*, and an internal *mucosal* layer. The *serosa* is a layer of peritoneum with subjacent areolar tissue. The *muscular layer* consists of external longitudinal and internal circular strata of nonstriated muscle; in addition an internal longitudinal group of fibres appears in some parts of the tube. The uterine or intramural region has attracted much attention (Lisa *et al.* 1954; Sweeney 1962), because of the idea that a sphincter might exist to cut off the uterine cavity from the tube and peritoneum as a guard against infection. The two extensive studies quoted revealed no intramural sphincter, but the occurrence of internal longitudinal fibres was confirmed. The isthmus, however, has the thickest muscular layer of any part of the uterine tube, there being a most marked reduction in this as the isthmus continues into the ampulla. The thickness of the muscle here largely affects the circular stratum; and it is here that the lumen of the tube is usually smallest, varying according to different observations from 0·1 to 1·0 mm. The mucosa is less complexly folded in the isthmus, there usually being three to six primary folds. There is considerable evidence that this stretch of the tube acts as a sphincteric mechanism which delays the progress of the segmenting zygote towards the uterus, perhaps to ensure that the former has reached a sufficient stage of development to implant in the endometrium. (The interesting suggestion has been made that a pharmacological agent capable of overruling this sphincteric activity might be valuable as a post-coital contraceptive—Mastroianni 1962.) In the ampullary part of the uterine tube the internal longitudinal muscle is absent, and the external longitudinal and circular fibres are considerably intermingled. The musculature of the infundibulum is similar in arrangement, but attempts to explain movements to appose the fimbriae to the ovary have entailed a variety of descriptions, none of which are as yet convincing. A sphincter at the abdominal ostium of the tube has been described (Whitelaw 1933; Woodruff and Pauerstein 1969), on the basis of experimental distension, but no histological confirmation of this has been clearly established.

The *mucous membrane* of the uterine tube consists of an epithelium and an underlying connective tissue stratum containing the mucosal blood and lymph vessels and nerve fibres. The epithelium is classically described as columnar and ciliated, but at least three kinds of cells can be identified, of which only one is ciliated, the others being secretory and 'intercalary'. At their basal aspects these cells adjoin an incomplete basement membrane. The intercalary cells, and another undifferentiated type with a darkly staining nucleus (Pauerstein and Woodruff 1967), may be precursors of the secretory cells, or exhausted remnants of them. The ultrastructural details of the ciliated cells present no peculiarities (pp. 18–20); the secretory cells show variations during the menstrual cycle, observable by both light (Snyder 1924) and electron (Hashimoto *et al.* 1960) microscopy. Briefly, these indicate increased secretory preparation during the follicular phase, and augmented secretory discharge during the luteal phase of the menstrual cycle.

The epithelium of the uterine tube is invaginated into the lumen of the tube in a series of major plicae or folds, each of which displays secondary and even tertiary projections. Thus, in transverse sections (**8**.180) the lumen is extensively invaded by plicae, each with its core of connective tissue, capillaries and supporting vessels. The functional role of the tube is, of course, the transport of ova and spermatozoa, and their joint product, the zygote, and the pre-implantation morula and blastocyst (p. 103) into which it develops. Moreover, both spermatozoa and ova, but especially the former, must be maintained in a viable state prior to fertilization; and similarly, the developing blastocyst, although perhaps more dependent upon its own nutritional resources, must

8.181 A radiograph of the uterus and uterine tubes after the introduction of a radio-opaque contrast medium through a cannula passed through the vagina into the cervix uteri. The shadow of the cannula is visible; above this is the triangular cavity of the uterine body and fundus. From the superior angles the lumina of the narrow (less than 1·0 mm diameter) intramural and isthmic parts of the uterine tubes may be traced inferolaterally, where they expand into the wider (2–4 mm diameter) ampullary parts of the tubes. Some contrast medium has escaped into the pelvic cavity from the abdominal ostia. (Radiograph kindly provided by Dr. J. Hilliger Smitham, Chelsea Hospital for Women, London.)

be maintained in a fluid environment entirely adapted to its needs. A great amount of research has been applied to the dynamics of these activities, details of which are beyond the scope of this text. No explanations are yet forthcoming as to why such large numbers of spermatozoa are required, or why relatively so few actually reach the ampulla, where they await the ovum and fertilize it. The fluid in the tube acts as an intermediary for respiratory gases in the case of spermatozoa, whose demands are high, and doubtless for its other passengers. Capacitation (p. 97) also occurs in the tube. The details of the entry of ova into the tube are still uncertain; direct conveyance by fimbriae, suction due to ciliary action, and so on, have been suggested, but convincing evidence is scant. The highly plicated nature of the tubal epithelium, the isthmic sphincter, and other details, obviously accord with the necessities of interchange of gases, nutrients and hormones, and with the delay necessary to ensure blastocyst development for implantation; but the immediate mechanisms are by no means clear. The contractile patterns, and the effects on them of nerve supplies, hormones (oestrogens and progesterone), and transmitter substances, have been widely investigated in experimental animals; details must be sought in appropriate papers and monographs.

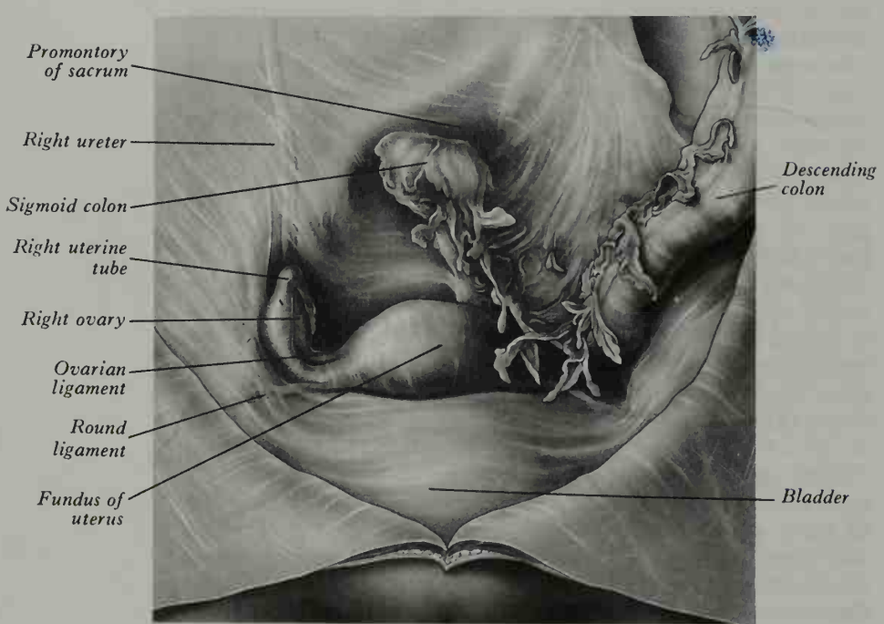
The arrest of the zygote at the isthmo-ampullary junction, the so-called 'isthmic block', has attracted special attention. It seems probable that the isthmic sphincter is adrenergic, like many other sphincters in other organs. Histochemical and experimental findings suggest that there is no cholinergic control in some parts, at least, of the human uterine tube (Nakanishi *et al.* 1967). Prostaglandins (pp. 97, 1397), which occur in the plasma of human semen, stimulate the muscle in the proximal part of the tube and inhibit it in the more distal (ampullary) region. All these studies are continuing, and doubtless more precise information will soon become available.

Vessels and nerves. The arterial and venous vessels of the uterine tube are basically derived from the *ovarian* and *uterine* stems. Some disagreements as to how much is supplied by the two arteries are apparent in the reports and results of different observers, and it has even been claimed that the intramural part of the tube is supplied by the ovarian artery. There is, however, convincing arteriographic evidence (Borell and Fernstrom 1953) that the uterine artery usually supplies about the medial two-thirds of the tube, the ovarian artery the remainder, though the partition between the two sources (which in any case anastomose) is somewhat variable. (For a detailed study of the arteries of the uterine tube consult Koritke *et al.* 1967.) The *veins* are arranged similarly; intrinsic networks in the mucosa, muscular layer and subserosa have been described (Gatsalov 1963; Koritké *et al.* 1967). The *lymphatic drainage* follows the veins (p. 798); its intrinsic details have been extensively described (Sampson 1937; Gatsalov 1963). The *nerve supply*, which, of course, largely reaches the uterine tube along the ovarian and uterine arteries, shows a correspondingly similar pattern of distribution. Most parts of the tube appear to receive both sympathetic and parasympathetic supplies; in the case of the latter, vagal fibres reach the lateral half of the tube, pelvic splanchnic fibres the medial moiety. The sympathetic supply is from the tenth thoracic to second lumbar segments of the spinal cord. The afferent fibres travel along the same path as the sympathetic motor supply and enter the cord through the eleventh thoracic to second lumbar dorsal nerve roots. Modified Pacinian corpuscles have been noted in the submucous connective tissue of the ampulla of the tube (Chiara 1959). The details of the tubal intrinsic innervation have been studied by metallic impregnations (Chiara 1959; Damiani *et al.* 1961), and more recently by fluorescence microscopy (Owman and Capodacqua 1967; Kubo 1970). The sympathetic nerves associated with the uterine tube are composed of postganglionic fibres, as well as the visceral afferents referred to above. The parasympathetic supply must form synapses, but ganglia have not been reliably reported in the wall or vicinity of the tube; the locus of relay may be in the paracervical ganglia. It is said that afferent autonomic fibres also accompany the parasympathetic nerves of the uterine tube.

Applied Anatomy. Pelvic peritonitis is said to occur more frequently in the female than in the male, because infective conditions of the vagina, uterus or uterine tube may involve the peritoneum by direct spread, owing to the communication which exists between the peritoneal cavity and the lumen of the tube through the abdominal ostium. Pus in the recto-uterine pouch may be palpated through the posterior fornix of the vagina.

Tubal inflammation (*salpingitis*) is usually due to infections which have spread upwards by way of the vagina and uterus. In some cases the fimbriated end of the tube may become closed by adhesions and a collection of pus forms in the tube (*pyosalpinx*).

Fertilization of the ovum (p. 100) usually occurs in the ampulla of the uterine tube, and normally the segmenting zygote is then passed on into the uterus; however, it may adhere to and undergo development in the tube, giving rise to the commonest variety of *ectopic gestation* (p. 110). In such cases the amnion and chorion are



formed, but a true decidua never develops; the gestation usually ends by extrusion of the ovum through the abdominal ostium, although it is not uncommon for the tube to rupture into the peritoneal cavity, this being accompanied by severe haemorrhage, necessitating surgical interference. For further information *see* Pauerstein and Woodruff 1967; Woodruff and Pauerstein 1969.

The Uterus

The uterus (**8**.176, 182, 183) is a hollow, thick-walled, muscular organ normally located entirely in the lesser pelvis between the urinary bladder in front and the rectum behind. Into its upper part the uterine tubes open, one on each side, while below, its cavity communicates with that of the vagina. When the ova are discharged from the ovaries they are carried to the uterine cavity through the uterine tubes. If an ovum be fertilized it embeds itself in the uterine wall and is normally retained in the uterus until prenatal development is completed, the uterus undergoing changes in size and structure to accommodate itself to the needs of the growing embryo and fetus. After parturition the uterus returns almost to its former condition, though it is somewhat larger than in the nulliparous state.

In the *adult nulliparous state* the uterus is flattened from before backwards and is piriform, with the narrow end being postero-inferior. It lies between the bladder antero-inferiorly, and the sigmoid colon and rectum posterosuperiorly, and is completely below the level of the pelvic inlet.

The long axis of the uterus usually lies approximately in the axis

8.182 A female pelvis and its contents. Anterosuperior view.

of the pelvic *inlet* (p. 384), but as the organ is freely movable its position necessarily varies with the state of distension of the bladder and rectum. Except when much displaced by a distended bladder, it forms almost a right angle with the vagina, since the axis of the vagina corresponds to the axes of the cavity and *outlet* of the lesser pelvis (p. 385).

The uterus measures about 7·5 cm in length, 5 cm in breadth at its widest, superior level, and nearly 2·5 cm in thickness; it weighs from 30 to 40 gm. It is divisible into two regions. On the surface, a little below the middle, there is a slight constriction, which corresponds to a narrowing of the uterine cavity, named the *internal os* of the uterus. The part above the internal os is termed the *corpus* or *body*, and that below, the *cervix*. The part of the body which lies above a plane passing through the points of entrance of the uterine tubes is known as the *fundus* (despite the fact that it is the *highest* part of the uterus. It is, however, the *deepest* region when approached through the cervix.)

The corpus uteri. The body gradually narrows from the fundus to the internal os. The *vesical*, or *anterior*, *surface* is in apposition with the urinary bladder. It is flattened and covered with peritoneum, which is reflected on to the bladder as the uterovesical fold at the level of the internal os. The recess between the bladder and the uterus is named the *vesico-uterine pouch*. It is usually empty, but may be occupied by a part of the intestine (p. 1323).

The *intestinal*, or *posterior*, *surface* is convex transversely, and is covered with peritoneum, which is continued downwards on the cervix uteri and the upper part of the vagina before being reflected backwards on to the rectum (**8**.183). It is related to the sigmoid colon, from which it is usually separated by the terminal coil of the ileum.

The *fundus* is convex like a dome, and covered with peritoneum continuous with that on the vesical and intestinal surfaces. Some coils of small intestine, and occasionally the distended sigmoid colon, are in contact with it.

The *lateral margins* or sides of the uterus are transversely convex. At the upper end of each the uterine tube passes through the uterine wall. Antero-inferior to this the round ligament of the uterus is attached; postero-inferior to it the ligament of the ovary is attached. These three structures lie within the broad ligament, which stretches from the margin of the uterus to the lateral wall of the pelvis (p. 1432).

The cervix uteri is about 2·5 cm in length; it is narrower and hence more cylindrical than the body, and is a little wider in the middle than above or below. Owing to its relationships it is less freely movable than the body, so that its long axis and that of the body are seldom in the same straight line. The long axis of the uterus as a whole presents the form of a curved line with its concavity forward, and the organ is described as being *anteflexed*. In extreme cases there may be an angular bend at the region of the internal os—acute anteflexion. When the bladder is empty the long axis of the cervix meets the long axis of the vagina at an angle which faces antero-inferiorly, and the whole uterus is therefore turned anteriorly on the vagina, or *anteverted*.

The cervix projects through the anterior wall of the vagina, which divides it into upper, supravaginal and lower, vaginal regions (**8**.183).

The *supravaginal part* of the cervix is separated *in front* from the bladder by cellular connective tissue, the *parametrium*, which extends also on to the sides of the cervix, and laterally between the layers of the broad ligaments. The uterine arteries reach the lateral aspects of the cervix in this tissue, whilst on each side the ureter runs downwards and forwards in it at a distance of about 2 cm from the cervix (*see* p. 1402). The relationship of the arteries and the ureters is not always symmetrical, and in particular one or other of the ureters may be somewhat anterior to the cervix. *Posteriorly* the supravaginal cervix is covered with peritoneum, which is prolonged below on to the posterior vaginal wall, whence it is reflected to the rectum, forming the *recto-uterine recess* (**8**.183). It is in relation with the rectum, from which it may be separated by the terminal coil of the ileum.

The *vaginal part* of the cervix projects into the anterior wall of the vagina forming the vaginal fornices (p. 1433). On its projecting rounded extremity there is a small, depressed, circular aperture, the *external os of the uterus*, through which the cavity of the cervix communicates with that of the vagina. In women who have borne children the external os is bounded by two lips, anterior and posterior, of which the anterior is the shorter and thicker, although, because of the slope of the cervix, it projects lower than the posterior. Normally both lips are in contact with the posterior vaginal wall.

The cavity of the uterus (**8**.181, 184) is small in comparison with the size of the organ, partly due to its thick wall.

The *cavity of the body* is a mere slit in sagittal section because the anterior and posterior walls are almost in contact. In coronal section it is seen to be triangular in shape, the base being formed by the internal surface of the fundus between the orifices of the uterine tubes, the apex by the internal os of the uterus; through this orifice the cavity of the body communicates with the canal of the cervix (**8**.183).

The *canal of the cervix* is somewhat fusiform, flattened from before backwards, and broader in the middle than at the ends. It

communicates above, through the *internal os*, with the cavity of the body, and below, through the *external os*, with the vaginal cavity. A longitudinal ridge is a feature of both the anterior and posterior walls of the canal and from each a number of small oblique *palmate folds* ascend laterally, giving the appearance of branches from the stem of a tree (*arbor vitae uteri*). The folds on the two walls are not opposed, but fit between one another so as to close the cervical canal.

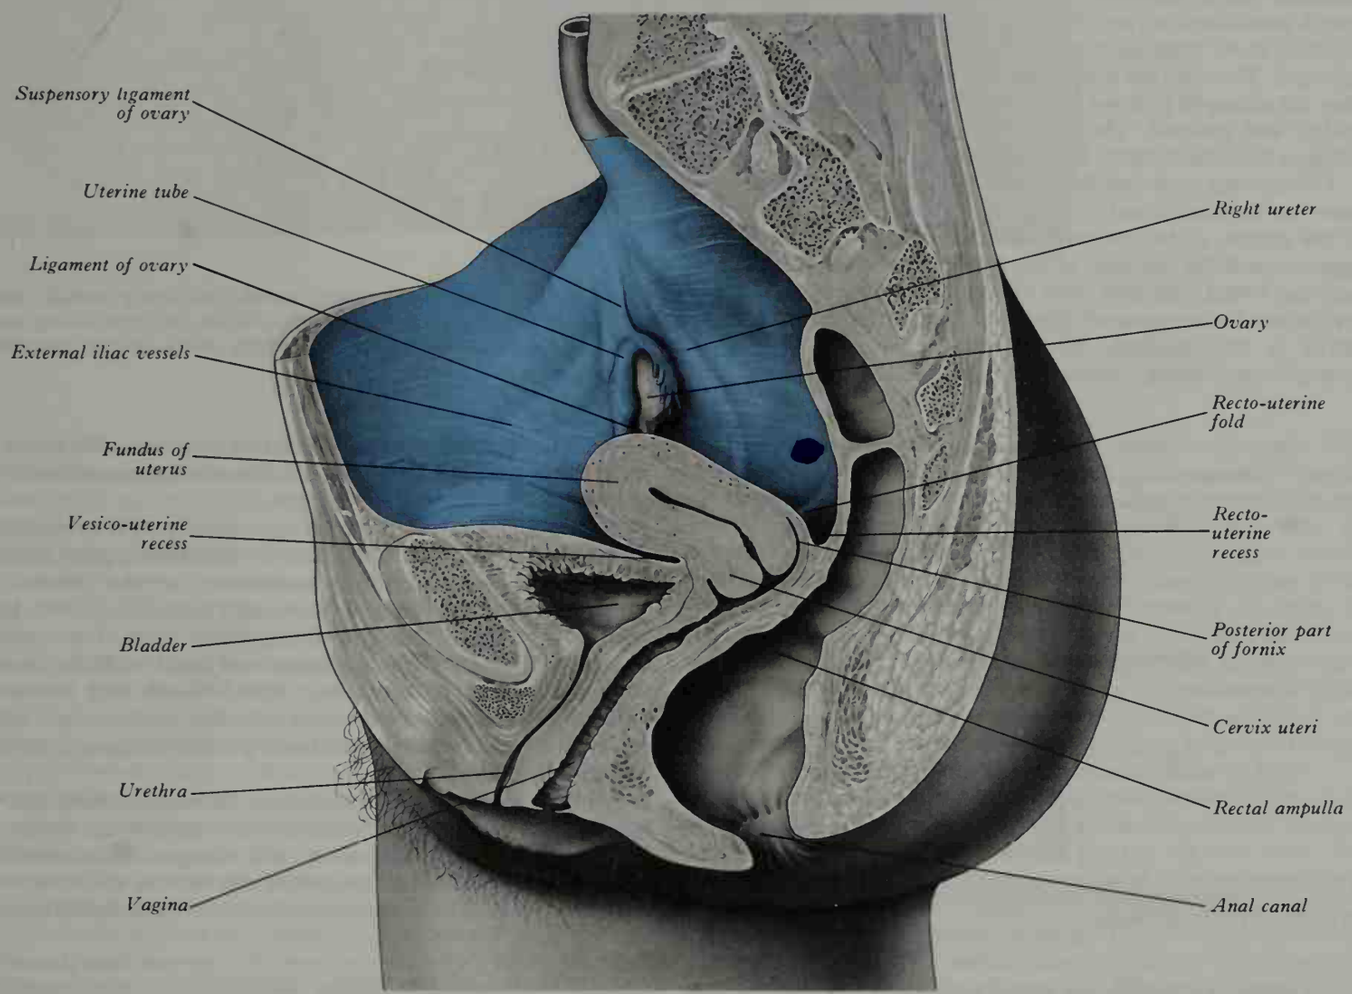
The total length of the uterine cavity from the external os to the fundus is about 6 cm.

Approximately the upper third of the cervix has been termed the *isthmus*, because it presents certain features which differentiate it from the rest (Stieve 1927; Frankl 1933). Although it is unaffected in the first month of pregnancy, it is gradually taken up into the body of the uterus during the second month and forms the '*lower uterine segment*' of British obstetricians. The fetal membranes, though firmly blended with the rest of the uterine mucosa, are not attached to the lower uterine segment. In the non-pregnant uterus the isthmus undergoes changes associated with menstruation similar to, but less pronounced than those which occur in the body of the organ. Histologically the isthmus resembles the body more than it resembles the cervix; its lining epithelium is low cylindrical in type and is ciliated; its mucous coat is thinner and the glands are fewer in number than they are in the cervix.

Age and reproductive changes. The form, size and situation of the uterus vary at different periods of life and in different circumstances.

In fetal life the uterus projects above the superior aperture of the lesser pelvis. The cervix is considerably larger than the body.

At puberty the uterus is piriform, and weighs from 14 to 17 gm. The fundus is just below the level of the superior pelvic aperture. The palmate folds are distinct, and extend to the upper part of the uterine cavity.



In the adult the position of the uterus is liable to considerable variation, depending chiefly on the condition of the bladder and rectum. When the bladder is empty the entire uterus is inclined anteriorly, and is at the same time curved at the junction of body and cervix, so that the body lies upon the bladder. As the latter fills, the uterus gradually becomes more and more erect, until with a fully distended bladder the fundus may be inclined towards the sacrum.

During menstruation the organ is slightly enlarged, and more vascular, and its surfaces are rounder; the external os is rounded, its lips swollen, and the lining membrane of the body is a darker colour.

During pregnancy the uterus becomes enormously enlarged, and in the eighth month reaches the epigastric region. The increase in size is mainly due to hypertrophy of pre-existing muscular fibres, and partly to development of new fibres. As pregnancy proceeds, the wall of the uterus becomes progressively thinner.

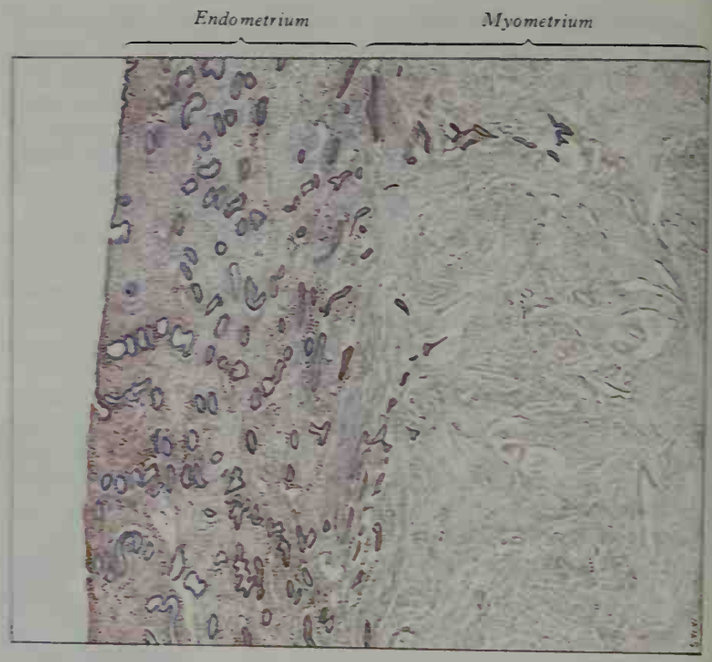
After parturition the uterus nearly regains its usual size, weighing about 42 gm; but its cavity is larger than in the nulliparous state, its vessels are tortuous, and its muscular layers are a little thicker and more defined; the external os is more prominent, and its edges present one or more fissures.

In old age the uterus becomes atrophied, paler, and denser in texture; a more distinct constriction separates the body and cervix. The internal os is frequently, and the external os occasionally, obliterated, whilst the lips of the external os almost entirely disappear.

8.183 A median sagittal section through a human female pelvis. The peritoneum is shown in blue.

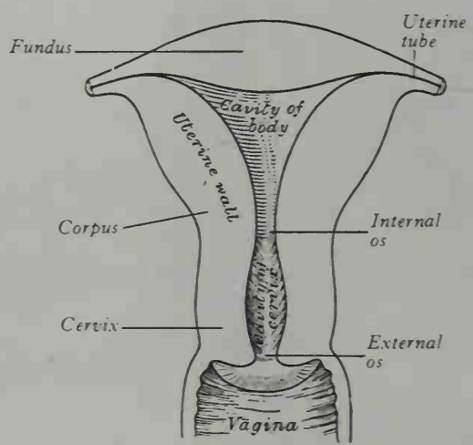
Structure. The uterine wall consists of three tissue strata, an external serous, a middle muscular, and an internal mucous layer.

The *serous layer* (*perimetrium*) is the peritoneum which posteriorly covers the body and supravaginal part of the cervix, but in front covers the body only. In the lower quarter of the posterior surface the peritoneum is not closely connected with the uterus, being separated from it by a layer of loose cellular tissue and some large veins. Beneath the serous covering is a subserous layer of areolar tissue.



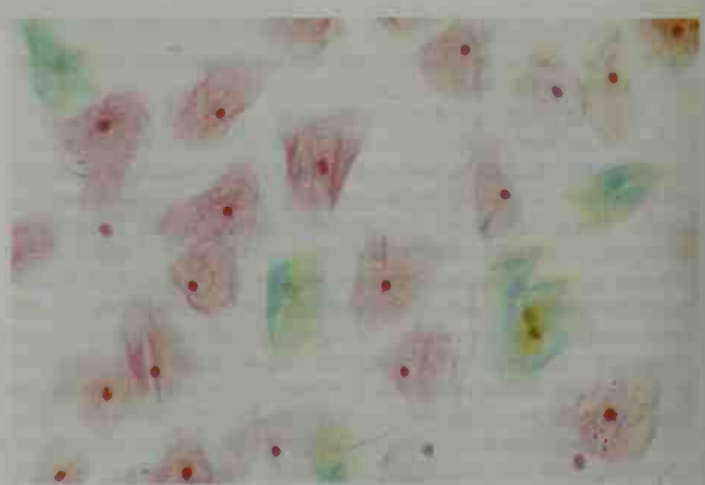
The *muscular layer* (or *myometrium*) forms most of the substance of the uterus. In nulliparae it is dense, firm, of a greyish colour, and (in the fixed state) cuts almost like cartilage. It is about 1·25 cm thick at the middle of the body and fundus, and thin at the orifices of the uterine tubes. It consists of bundles of nonstriated muscular fibres, intermixed with areolar tissue, blood vessels, lymph vessels and nerves. During pregnancy the muscular tissue becomes more prominently developed, the fibres being greatly enlarged. Although the muscular fibres interlace in all directions, they are arranged in three more or less distinct layers: external, middle and internal. The muscle of the cervix contains more collagen and elastin fibres than that of the body.

The external layer consists chiefly of longitudinal fibres, which pass over the fundus and converge at the lateral angle on each side of the uterus, to be continued on the uterine tube, the round ligament and the ligament of the ovary; some pass on each side into the broad ligament, and others run backwards from the cervix into the uterosacral ligaments. The intermediate layer of fibres is the thickest, but presents no regularity in its arrangement, being disposed longitudinally, obliquely and transversely; it contains the larger blood vessels. The internal layer consists of longitudinal and circular fibres. The deep ends of the uterine glands come into close relation with the fibres of the internal layer. An infundibular arrangement of elastin and nonstriated muscle fibres has been described in the cervix, with its narrow extremity adjacent to the external os (Hamperl 1970). It is considered that this may be able to exert a valvular effect in keeping the os normally closed. Toth (1977) has described bilateral longitudinal fascicles of nonstriated muscle embedded in the wall of the uterus, one on each side in the lateral region and extending from the fundal angle to the cervix. They are said to be largely submucosal. Each fascicle consists, in its juxtafundal part, of a number of somewhat dispersed sub-fascicles; but the bundle is more compact as it approaches the cervix. In places, epithelial rests were observed in the axis of the bundle, and it is suggested that the origin of the structure may be mesonephric. The muscle cells of the bundle ('*fasciculus cervico-angularis*') are structurally different from those of the myometrium proper, and this has prompted the speculation that the fasciculus may function as a relatively fast conducting pathway in the integration of uterine muscular activity. Confirmation and expansion of these findings will be awaited with interest.

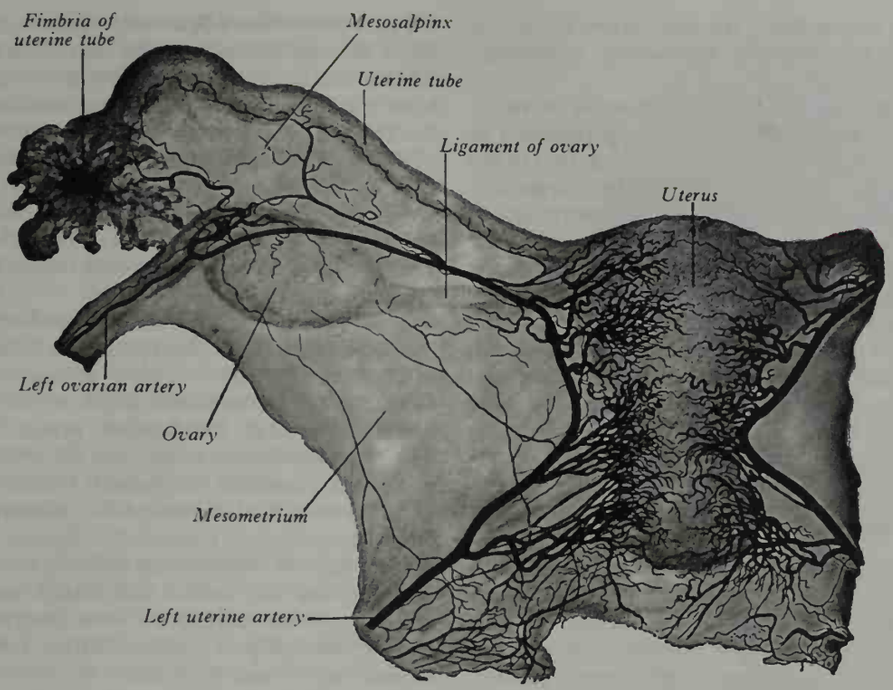


The *mucous membrane* or *endometrium* (**8**.185) of the uterus is continuous, through the fimbriated extremities of the uterine tubes, with the peritoneum, and, through the external os of the uterus, with the mucosa of the vagina.

In the body of the uterus the mucous membrane is covered with columnar epithelium. Prior to puberty the epithelium is ciliated, but owing to its periodic destruction in the process of menstruation and pregnancy it is usually non-ciliated over large areas in the adult uterus. The subepithelial layer of the mucosa consists of an embryonic, nucleated and highly cellular form of connective tissue in which run blood vessels and numerous lymphatic spaces. It contains many tube-like *uterine glands*, which are lined with columnar epithelium, patchily ciliated, and open into the cavity of the uterus.



Cyclical changes in the endometrium. Between puberty and the menopause, in each lunar month, the endometrium lining the body of the uterus undergoes cyclical changes which constitute the *menstrual cycle*. The duration of a menstrual cycle may vary from individual to individual, or in the same individual from cycle



8.185 Section of human endometrium and underlying musculature in the interval phase. Note that some glands extend into the more internal layers of the myometrium. Stained with haematoxylin and eosin. Magnification about × 20.

8.184 Sectional diagram showing the interior divisions of the uterus and its continuity with the vagina.

8.186 Cells of the mature vaginal epithelium in a diagnostic smear preparation stained by Papanicolaou's technique (Shorr modification). All the cells shown are superficial keratinizing squames, some of which show actual keratin granules. The pink cells are the oldest and most superficial. (Preparation kindly provided by Dr. Max Levene, St. Helier Hospital, Carshalton.)

8.187 Posterior aspect of a cleared injected specimen (prepared by Dr. Hamilton Drummond) to show the distribution of the left uterine and ovarian arteries of a female aged seventeen and a half years.

to cycle. The details of the histological changes, the hormonal factors influencing them and the variations that may occur in the cycles are described in the section of this volume devoted to Embryology (pp. 126–130).

In the upper two-thirds of the cervix, the mucous membrane is provided with numerous, deep, glandular follicles which secrete a clear, viscid, alkaline mucus; in addition, extending through the whole length of the canal, a variable number of little cysts are found, presumably follicles which have become occluded and distended with retained secretion. They are called the *ovula Nabothi*. The mucous membrane covering the lower one-half of the cervical canal presents numerous papillae. The epithelium of the upper two-thirds is cylindrical and ciliated, but below this it loses its cilia, and, close to the external os, changes to stratified squamous epithelium. On the vaginal surface of the cervix the epithelium is similar to that lining the vagina, viz. stratified squamous. The mucous membrane lining the lower two-thirds of the cervix does not undergo the (menstrual) cyclical changes such as occur in the body of the uterus (see also pp. 126–130).

Vessels and nerves. *The main arterial supply* to the whole of the uterus is by way of the two uterine branches of the internal iliac arteries (p. 720). These vessels anastomose superiorly with the ovarian and inferiorly with the vaginal arteries; and while this provides alternative channels, the predominance of the uterine arteries is emphasized by the fact that whilst they undergo marked hypertrophy during pregnancy, the other vessels mentioned do not. The two uterine arteries anastomose extensively with each other across the midline by small branches, and one or other stem artery can be ligated without serious interference with the blood supply (Siegel and Mengert 1961), and even more extensive ligations have been safely undertaken. The tortuosity of the uterine arteries, as they ascend in the broad ligaments, is repeated in their branches in the uterine wall; all these sinuosities straighten out as the uterus expands in pregnancy, but it is interesting to note that they are present in the nulliparous state. Each uterine artery produces large numbers of branches which pass at once into the uterine wall, dividing there into groups of *anterior* and *posterior arcuate arteries*. These pass circumferentially in the myometrium, and their terminal branches anastomose across the midline with similar vessels from the opposite side (**8**.187). This entails that both the anterior and posterior aspects of the uterus show considerable zones in the median region which are free of larger vessels; these zones are sometimes referred to as relatively avascular—a misleading and erroneous concept. The arcuate arteries supply large numbers of tortuous *radial branches* which travel centripetally through the deeper myometrial layers, supplying these *en route*, to reach the endometrium. As microradiographic and injection techniques show, these vessels provide the basis of a very rich series of capillary plexuses in the myometrium and endometrium (Farrer-Brown *et al.* 1970). In the myometrium numerous *spiral* or helical arteriolar branches of the radial arteries pass towards and supply the endometrium, their form being affected considerably by the endometrial cycle. During the proliferative phase the spiral arterioles are much less prominent; in the secretory phase they appear to grow in length and calibre and become even more tortuous (Ramsey 1955).

The *uterine veins* are arranged upon a plan similar to that of the arteries (Farrer-Brown *et al.* 1970). Volumetrically they are even more prominent than the arteries in the uterine wall. The occurrence of minute venous sinuses or lakes in the endometrium, where they are a constant feature in the pregnant uterus, has been recorded in the resting uterus (Schlegel 1946) but not confirmed. During pregnancy, the *ovarian veins*, unlike the accompanying arteries, may be noticeably enlarged (O'Leary and O'Leary 1966).

The *lymphatic vessels* and drainage of the uterus are described on p. 798. The intrinsic lymphatic plexuses of the uterine wall have been little studied in the human female. A most detailed injection study of primate arrangements concerns the macaque monkey (Wislocki and Dempsey 1939).

The *nerves* supplying the uterus have been described on p. 1136. The autonomic supply is derived directly from the ovarian and hypogastric plexuses; the sympathetic preganglionic fibres are axons of nerve cells in the twelfth thoracic and first lumbar spinal segments; the parasympathetic preganglionic axons issue in the second, third and fourth ventral spinal roots of the sacral cord. Whilst there is general agreement as to the pathways by which autonomic fibres reach the uterus, the details of their distribution and physiological effects are still ill-defined. Both cholinergic and adrenergic fibres have been identified in the muscular and submucous strata of the cervix, the former predominating. A number of observers consider that the corpus uteri is innervated only by sympathetic nerves. In a histochemical study (Owman *et al.* 1967), only adrenergic nerve terminals were considered to be present in most parts of the female internal genitalia, including the uterus. The effects of the uterine innervation are also complicated by hormonal influences and by

the evocation of different responses by the same active agent (for example, adrenalin) under differing prevailing conditions (Wansbrough *et al.* 1967).

Applied Anatomy. A certain degree of *anteversion* or *retroversion* of the uterus can take place without being regarded as pathological; but when the degree of flexion at the junction of the body with the cervix becomes considerable it must be so regarded. This is especially true of retroversion combined with retroflexion. Retroversion alone is a posterior inclination of the whole uterus, so that the cervix points forwards towards the os pubis; retroflexion is a posterior curvature of the body only, at its junction with the cervix. The two conditions are usually combined. Prolapse of the uterus is another common condition. The organ sinks to an abnormally low level in the pelvis, and sometimes protrudes beyond the vulva. This condition is usually due to imperfect repair of the pelvic floor following injury of the perineum during parturition (p. 561).

THE UTERINE LIGAMENTS

The uterus is connected to the bladder, the rectum and the walls of the lesser pelvis by a number of 'ligaments'; some of these are merely peritoneal folds and have little ligamentous effect, whilst others consist of nonstriated muscle and fibrous tissue and can function as real ties, with also some measure of dynamic control.

The *anterior ligament* consists of the *uterovesical fold* of peritoneum, which is reflected on to the upper surface of the bladder from the front of the uterus, at the junction of the cervix and body.

The *posterior ligament* consists of the *rectovaginal fold* of peritoneum, which is reflected from the back of the posterior fornix of the vagina on to the front of the rectum. It forms the bottom of the deep *recto-uterine pouch* which is bounded anteriorly by the posterior wall of the body of the uterus, the supravaginal portion of the cervix uteri and the posterior fornix of the vagina; posteriorly, by the rectum; laterally, by two crescentic folds of peritoneum which pass backwards from the cervix uteri, one on each side of the rectum, to the posterior wall of the lesser pelvis. These are the *recto-uterine folds* and they contain a considerable amount of fibrous tissue and nonstriated muscular fibres, which are attached to the front of the sacrum and constitute the *uterosacral ligaments*. On rectal examination the uterosacral ligaments can be palpated as they pass backwards at the sides of the rectum.

The two **broad ligaments** (**8**.176) pass from the sides of the uterus to the lateral walls of the pelvis. Together with the uterus they form a septum across the cavity of the lesser pelvis dividing it into two parts. The anterior part contains the bladder; the posterior part, the rectum, and usually, the terminal coil of the ileum and a part of the sigmoid colon.

When the bladder is empty or only slightly distended, the surfaces of the broad ligament are directed superiorly and inferiorly and it has a free anterior and an attached posterior border. As the bladder fills, the plane of the ligament alters and its free border becomes superior in position. In this condition of the bladder, the broad ligament consists of anterior and posterior layers, which are continuous with each other at its upper, free border, and diverge from each other below, where they approach the superior surface of the levator ani. The uterine tube is contained in the free border, and the part of the ligament between the tube and the ligament of the ovary and mesovarium is termed the *mesosalpinx*. The infundibulum of the tube projects from the free border near its lateral extremity. The ovary is attached to the posterior layer by the *mesovarium*. The part of the broad ligament which extends from the infundibulum of the tube and the upper pole of the ovary to the lateral wall of the lesser pelvis contains the ovarian blood vessels, nerves and lymph vessels and is named the *suspensory ligament of the ovary* (in some respects a less appropriate term than the older, but unofficial, *infundibulopelvic ligament*). It is continued laterally over the external iliac vessels as a distinct fold. Between the ovary and the uterine tube, the mesosalpinx contains the epoöphoron (p. 1425) and, at its medial end, the paroöphoron (p. 1425) and anastomosing branches of the uterine and ovarian vessels. The term *mesometrium* is applied to the part of the broad ligament extending from the pelvic floor to the ovary, the ligament of the ovary and the body of the uterus. The uterine artery passes between the layers of the broad ligament at its inferior border, about 1·5 cm lateral to the cervix and after it has crossed the ureter (p. 720). It then ascends in the medial part of the ligament and turns laterally below the uterine tube to anastomose with the ovarian artery. In addition to all the structures already enumerated, the broad ligament encloses the ligament of the ovary (p. 1423), the proximal part of the round ligament of the uterus and some nonstriated muscle and fibroareolar tissue.

The *round ligaments* of the uterus (**8**.182) are two narrow, flat bands between 10 cm and 12 cm long, situated between the layers of the broad ligament in front of and below the uterine tubes. Commencing at the lateral angle of the uterus each ligament is directed forwards and laterally across the vesical vessels, the obturator vessels and nerve, and the obliterated umbilical artery and over the external iliac vessels. It then passes through the deep inguinal ring, hooking round the commencement of the inferior epigastric artery, to traverse the inguinal canal. It finally breaks up into strands which merge with the areolar tissue in the labium majus. Near the uterus the round ligament contains much nonstriated muscle; this becomes progressively less in amount and the terminal part is purely fibrous. It is accompanied by blood vessels, nerves and lymphatics; the latter drain from the parts of the uterus near the entry of the uterine tube and pass to the superficial inguinal lymph nodes (p. 791), and malignant disease of the uterus may spread along this route. In the fetus a tubular process of the peritoneum (*processus vaginalis*) is carried with it for a short distance into the inguinal canal. The processus vaginalis is generally obliterated in the adult, but sometimes remains patent even in advanced life. It is homologous with the peritoneal processus which precedes the descent of the testis.

In its passage through the inguinal canal, the round ligament receives coverings corresponding to those related to the spermatic cord in the male (p. 1418), though they are thinner and blend with the ligament itself; the ligament may even fail to reach the labium majus and end by fusing with these coverings.

The round ligament and the ligament of the ovary are together homologous with the gubernaculum testis in the male (p. 218).

The *transverse cervical ligament* (of Mackenrodt) is attached to the side of the cervix uteri and to the vault and lateral fornix of the vagina, and is continuous with the fibrous tissue which surrounds the pelvic blood vessels, probably playing a considerable part in maintaining the position of the uterus. It is of importance in gynaecological surgery. Other dense parts of the pelvic fascia connect the cervix of the uterus and the upper part of the vagina to the posterior aspect of the pubis.

While the above ligaments (as well as the vagina) act in varying (and undetermined) measure as mechanical supports for the uterus, maintaining it in its normal position, the levatores ani and coccygei, the muscles of the urogenital diaphragm and the perineal body appear to be of particular importance in this respect. For the role of the musculature of the pelvic floor consult a review and discussion by Wendell-Smith and Wilson (1977).

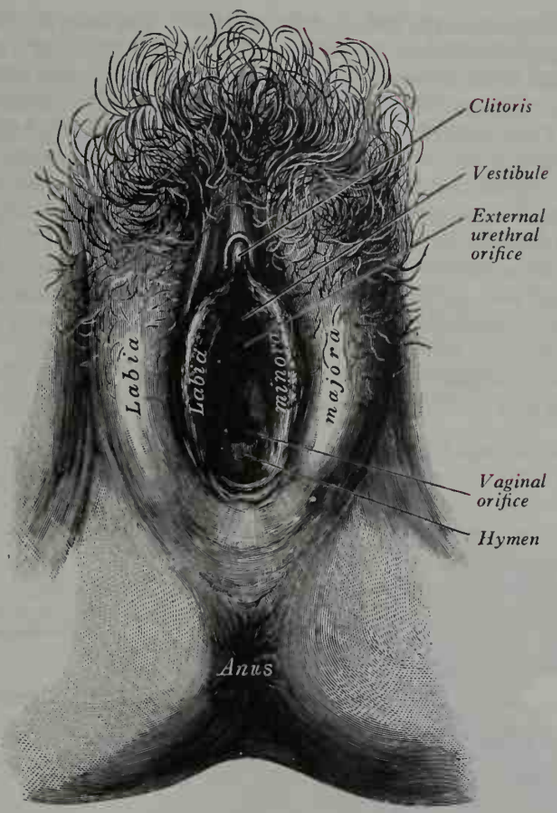
The Vagina

The vagina (**8**.183), the female organ of copulation, is a fibromuscular tube lined with a stratified epithelium, which extends from the vestibule, or cleft between the labia minora, to the uterus, and is situated between the bladder and urethra anteriorly, and the rectum and anal canal posteriorly; it is inclined posterosuperiorly, its axis forming with that of the uterus an angle of over ninety degrees, opening anteriorly, but which varies with the conditions of the bladder and rectum. Its walls are ordinarily in contact, and the usual shape of its lower part on transverse section is that of an H, but the transverse limb being slightly curved forwards or backwards, while the lateral limbs are somewhat convex towards the median plane; its middle part has the appearance of a transverse slit. Its length is 7·5 cm along its anterior wall, and 9 cm along its posterior wall; its width gradually increases from below upwards. Its upper end surrounds the

vaginal portion of the cervix uteri a short distance from the external os of the uterus, its attachment extending higher on the posterior than on the anterior wall of the cervix. To the arched recess between the cervix uteri and vagina the term *fornix* is applied; anterior, posterior and lateral parts of this annular groove are often so designated, but the groove is essentially continuous.

The *anterior* part of the vaginal wall is in relation with the base of the bladder, and with the urethra, which is actually embedded in the anterior wall of the vagina. The *posterior part* of the vaginal wall, which is covered with peritoneum in its upper quarter, is separated from the rectum by the recto-uterine pouch above, and by some loose fibro-areolar tissue in its middle half; the lower quarter is separated from the anal canal by a mass of muscular and fibrous tissue, the *perineal body*. At the sides are the levatores ani (p. 561) and pelvic fascia. As the terminations of the ureters pass forwards and medially to reach the fundus of the bladder, they are close to the lateral fornices of the vagina, and as they enter the bladder are usually placed in front of the vagina (p. 1402). The ureter is crossed transversely in this situation by the uterine artery (p. 720).

Structure. The vagina consists of a mucous membrane and a muscular stratum, the lamina propria of the former containing in its deepest layer a large number of thin-walled veins.



The *mucous membrane* is firmly fixed to the muscular layer; on its epithelial surface there are two median longitudinal ridges, one on the anterior and the other on the posterior wall of the vagina. These ridges are called the *vaginal columns*, and from them numerous transverse ridges or rugae extend laterally on each side. These rugae are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded with conical projections or papillae; they are most numerous on the posterior wall and near the orifice of the vagina, especially before parturition. The epithelium of the mucous membrane is of the non-keratinized, stratified squamous variety. After puberty it becomes thick and is rich in glycogen. Unlike the condition in many mammals, the vaginal epithelium does not undergo very marked changes during the menstrual cycle; its glycogen increases in the post-ovulatory phase and diminishes towards the end of the cycle. The fermentative action of certain bacteria (Döderlein's bacillus) on the glycogen renders the fluid in the vagina acid. There are no glands in the vaginal mucous membrane, which is thus lubricated by mucus derived from the glands of the cervix of the uterus.

Cyclical variations in the vaginal epithelium have been studied extensively in a number of animals, and in man, by taking specimens or 'smears' to examine the cell types and their relative frequencies (Stockard and Papanicolaou 1917). The cells observed are mostly epithelial cells and leucocytes (**8**.186). This technique has proved most fruitful in reproductive studies in experimental animals, and also in clinical medicine. The effects of hormonal therapy are clearly reflected in changes in the vaginal cellular débris. The method has also been extended to serve as an early warning of uterine carcinoma, especially of the cervix (Papanicolaou and Traut 1943). For developments in this technique consult Koss (1968).

The *muscular layers* are nonstriated: an external longitudinal, which is by far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscular fibres of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on each side. The two layers are not distinctly separable from one another, but are connected by oblique decussating fasciculi. In addition to this, the lower end of the vagina is surrounded by a band of striated muscular fibres, termed the *bulbospongiosus* (p. 563).

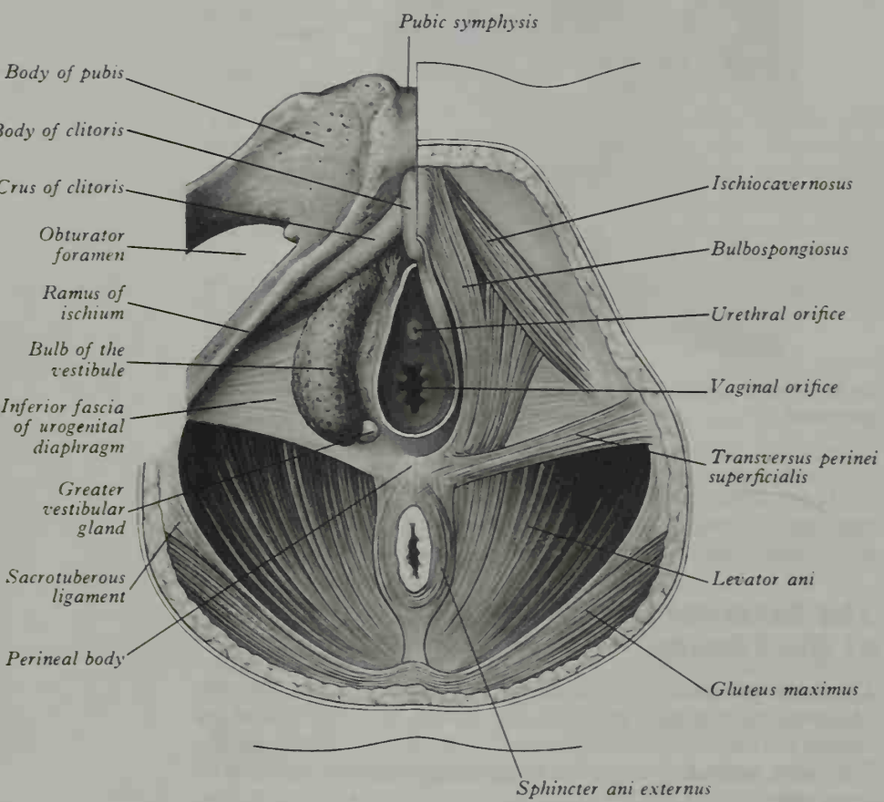
External to the muscular coat there is a layer of areolar tissue, containing a large plexus of blood vessels.

Vessels and nerves. The *arteries* of the vagina are derived from the vaginal, uterine, internal pudendal, and middle rectal branches of the internal iliac arteries (p. 720; **6**.94). The *veins* form plexuses at the sides of the vagina, and these plexuses are drained through the vaginal veins into the internal iliac veins. The *lymph vessels* are described on p. 798. The *nerves* are derived from the vaginal plexuses, and from the pelvic splanchnic nerves (p. 1135). The lower part of the vagina is supplied by the pudendal nerve (p. 1115). Many nerve fibres in the lamina propria and muscle coat react strongly to tests for cholinesterase and are probably of the cholinergic type.

8.188 Female external genitalia, with the labia majora et minora separated.

The External Genital Organs of the Female

The female external genitalia (**8**.188) include the mons pubis, the labia majora et minora pudendi, the clitoris, the vestibule of the vagina, the bulb of the vestibule and the greater vestibular glands. The term *pudendum* or *vulva*, as generally applied, includes all these parts.



The mons pubis, the rounded eminence in front of the pubis symphysis, is formed by a collection of subcutaneous adipose connective tissue. It becomes covered with coarse pubic hair at the time of puberty over an area which often has an approximately horizontal upper limit. In the male the *pubic* hair proper has a similar upper limit and its apparent continuation upwards to the umbilicus consists of ordinary body hair.

The labia majora are two prominent, longitudinal, cutaneous folds which extend from the mons pubis into the perineum and form the lateral boundaries of the *pudendal cleft*, into which the vagina and urethra open. Each labium has two surfaces—external, pigmented and covered with crisp hairs, and internal, smooth but studded with large sebaceous follicles. Between the two surfaces there is a considerable quantity of areolar and adipose tissue, and this is intermixed with nonstriated muscle fibres resembling the dartos muscle of the scrotum, together with vessels, nerves and glands. The round ligament of the uterus ends in the adipose tissue and skin of the front part of the labium. A peristent processus vaginalis and a congenital inguinal hernia may reach the labium. The labia are thicker in front, where they form by their meeting the *anterior commissure*. Posteriorly they are not really joined, but appear to become lost in the neighbouring skin, ending close to, and nearly parallel with, each other; together with the connecting skin between them, they form the *posterior commissure*, or posterior boundary of the pudendal fissure. The interval between the posterior commissure and the anus, from 2·5 to 3 cm in length, constitutes the '*gynaecological*' *perineum*.

The labia minora are two small cutaneous folds, devoid of fat,

situated between the labia majora, and extending from the clitoris obliquely downwards, laterally and backwards for about 4 cm on each side of the orifice of the vagina, between which and the labia majora they end; in the virgin the posterior ends of the labia minora are usually joined across the median plane by a fold of skin, named the *frenulum of the labia minora*. Anteriorly, each labium minus divides into two; the upper division passes above the clitoris to meet its fellow, forming a fold which overhangs the glans clitoridis and is named the *prepuce* of the clitoris; the lower division passes below the clitoris and is united to its under surface, forming, with its fellow of the opposite side, the *frenulum* of the clitoris. Numerous sebaceous follicles are placed on the opposed surfaces of the labia minora.

The vestibule is the cleft between the labia minora: in it the vaginal and external urethral orifices are situated, and, between them, numerous small mucous *lesser vestibular glands* open on the surface of the vestibule. The part of the vestibule between the vaginal orifice and the frenulum of the labia minora consists of a shallow depression named the *vestibular fossa*.

8.189 Dissection of the female perineum to show the bulb of the vestibule and greater vestibular gland on the right; on the left the muscles superficial to these structures have been left *in situ*.

The clitoris is an erectile structure, homologous with the penis. It is postero-inferior to the anterior commissure, partially enclosed between the anterior ends of the labia minora. The *body of the clitoris* consists of two corpora cavernosa, composed of erectile tissue enclosed in a dense layer of fibrous tissue, and separated along their medial surfaces by an incomplete fibrous *pectiniform septum*; each corpus cavernosum is connected to the pubic and ischial rami by a *crus*. The free extremity, or *glans clitoridis*, is a small rounded tubercle, consisting of spongy erectile tissue, and its epithelium has a highly developed cutaneous sensitivity, of considerable importance in sexual responses. The clitoris is provided, like the penis, with a 'suspensory' ligament, and with two small muscles, named the ischiocavernosi (p. 563), which are inserted into the crura of the clitoris. The clitoris is thus in many details a smaller version of the penis, but it differs basically in being entirely separate from the urethra.

The vaginal orifice (or *introitus*) is usually a median slit below and behind the opening of the urethra; its size varies inversely with that of the *hymen*. This orifice is, of course, like all parts of the vagina capable of great distension during parturition, and to a much lesser degree, during coitus.

The hymen vaginae is a thin fold of mucous membrane situated at the orifice of the vagina; the internal surfaces of the fold are normally in contact with each other, and the vaginal orifice appears as a cleft between them. The hymen varies much in shape and extent. When stretched, its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar fold, with its concave margin turned towards the pubes. Occasionally it is cribriform or its free margin forms a membranous fringe. It may be entirely absent, or may form a complete septum across the lower end of the vagina; the latter condition is known as an imperforate hymen. When the hymen has been ruptured, small rounded elevations known as the *carunculae hymenales* are found as its remains. The hymen has no known function.

The external urethral orifice is about 2·5 cm postero-inferior to the glans clitoridis and immediately anterior to the orifice of the vagina: it usually assumes the form of a short, sagittal cleft with slightly raised margins. It is markedly distensible.

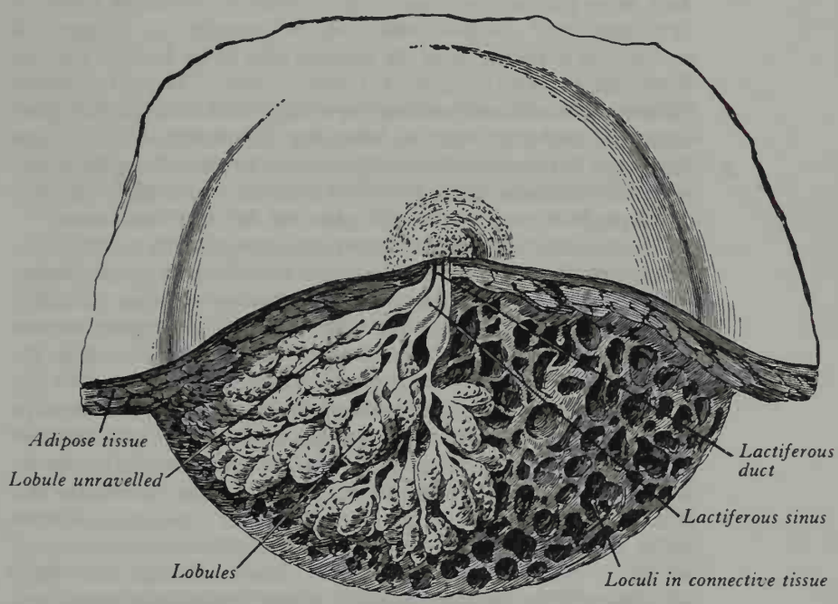
The bulbs of the vestibule (**8**.189) are the homologue of the single bulb of the penis and corpus spongiosum of the male. They are two elongated masses of erectile tissue, one on each side of the vaginal orifice and united to each other in front by a narrow median band termed the *commissura bulborum* (pars intermedia). Each lateral mass measures about 3 cm in length. Their posterior ends are expanded and are in contact with the greater vestibular glands; their anterior ends are tapered and joined to one another by the commissure and to the glans of the clitoris by two slender bands of erectile tissue; their deep surfaces are in contact with the inferior fascia of the urogenital diaphragm; superficially they are covered with the bulbospongiosus. Thus, in the female, the corpus spongiosum is, as it were, cleft into two bilateral masses, through all but its most anterior region, by the vestibule and the vaginal and urethral orifices.

The greater vestibular glands (**8**.189) are the homologues of the bulbo-urethral glands in the male. They consist of two small, round, or oval bodies of a reddish-yellow colour, situated one on each side of the vaginal orifice, in contact with, and often overlapped by, the posterior end of the lateral mass of the bulb of the vestibule. Each gland opens by means of a duct, about 2 cm long, immediately lateral to the hymen, in the groove between its attached border and the labium minus.

Vessels and nerves. The arterial blood supply, venous and lymph drainage and the nerve supply of the structures comprising the external genital organs of the female are similar to those relating to the homologous structures in the male. The arterial supply, from two external and one internal pudendal artery on each side, is potentially massive. Hence, haemorrhage from injuries of the vulva may be very severe. The different sensory innervation of the anterior and posterior parts of the labium majus resembles that of the scrotum (*see* p. 1418).

The Mammae or Mammary Glands

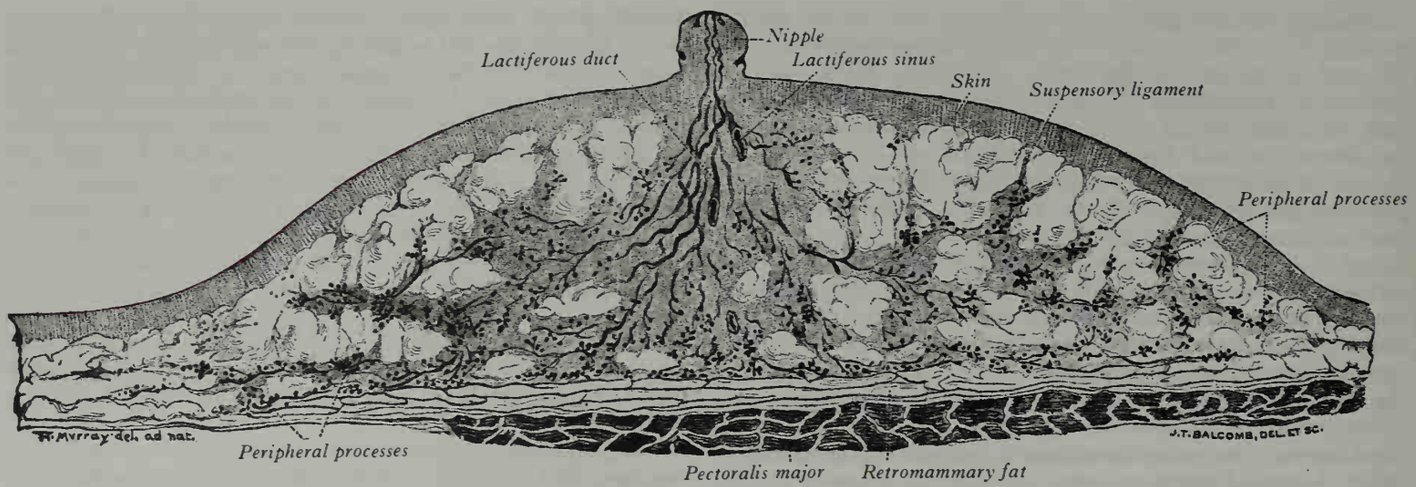
The mammae exist in both sexes. In the male they are rudimentary throughout life; in the female they are undeveloped before puberty, but undergo considerable growth and elaboration at and after puberty. They attain their greatest development during the later months of pregnancy and especially for some time after parturition, during lactation. The mamma consists of glandular tissue (the *mammary gland* proper), which secretes milk, and fibrous and adipose tissue in between the lobes and lobules of the glandular tissue, together with blood vessels, lymph vessels and nerves.



The female mamma or breast. In the young adult female, each breast forms a rounded eminence lying within the superficial fascia chiefly anterior to the thorax, but spreading variably on to its lateral aspect. Its shape varies markedly in different individuals, and races, and in the same individual at different ages. It may be hemispherical, conical, and is variably pendulous, becoming either piriform or thin and flattened. Most of its bulk is adipose tissue, except during lactation; and hence its shape and

consistency are primarily dependent upon this. In the lateral plane (**8**.91) its base extends vertically from the second to the sixth rib, and at the level of the fourth costal cartilage it extends transversely from the side of the sternum to near the mid-axillary line. The superolateral part of the breast is prolonged upwards and laterally towards the axilla, forming the *axillary tail*, which extends along the lower border of the pectoralis major and may pass through the deep fascia to lie in close relationship to the pectoral group of axillary lymph nodes. The deep aspect of the breast is slightly concave and is related to the pectoralis major, serratus anterior, obliquus externus abdominis and the aponeurosis of the latter muscle as it forms the anterior wall of the sheath of the rectus abdominis. The breast is, however, separated from these muscles by the deep fascia, and between the breast and the deep fascia there is a zone of loose areolar tissue, the *retromammary* or *submammary* '*space*', which allows the breast some degree of movement on the deep fascia covering pectoralis major. Advanced mammary carcinoma may, by invasion, fix the breast to the pectoralis major. Occasionally small projections of the mammary glandular tissue may penetrate through the deep fascia into the superficial part of this muscle. The *mammary papilla* or *nipple* is a cylindrical or conical projection from just below the centre of the anterior surface of the breast; it commonly lies at the level of the fourth intercostal space in nulliparous females. It is pink or light brown in colour and is traversed by fifteen to twenty lactiferous ducts, which open by minute orifices on its wrinkled tip. It contains numerous nonstriated muscle fibres; most of these are arranged circularly and their contraction when the papilla is mechanically stimulated (e.g. by suckling) causes erection of the papilla; other fibres are arranged longitudinally and their contraction may retract it. Occasionally the papilla may not evert during its prenatal development (p. 156) and thus remains permanently retracted, a condition that causes difficulty in suckling. The base of the papilla is encircled by a coloured area of skin called the *areola*, which is rose-pink in the nulliparous Caucasian female. During the second month of pregnancy it becomes larger and darker in colour and as pregnancy advances it becomes dark brown, the depth of the colour varying with the female's complexion; this colour diminishes in intensity after the end of lactation, but the areola never returns to its original hue. It contains numerous sebaceous *areolar glands*, which become much enlarged during pregnancy and lactation to form '*tubercles*' beneath the skin; the oily secretion of these glands provides a protective lubricant for the skin of the areola and papilla during lactation. Some of the glands appear to be intermediate in structure between the sebaceous and sweat varieties, whilst others (Montgomery's glands) are of the mammary type. There is no fat immediately beneath the skin of the areola and papilla.

STRUCTURE OF THE BREAST



The mammary gland (**8**.190–193) consists of: (*a*) glandular tissue of the tubulo-alveolar type; (*b*) fibrous tissue, connecting its lobes; (*c*) adipose tissue in the intervals between the lobes (Cowie 1974). The subcutaneous tissue encloses the gland (but does not form a distinct capsule) and sends numerous septa into it to support its various lobules. From the part of the fascia which covers the gland fibrous processes pass forwards to the skin and the papilla; these are better developed over the upper part of the breast and constitute the *suspensory ligaments* (of Cooper). These ligaments may become contracted by fibrosis in cancer of the breast, thus causing the overlying skin to become pitted and retracted. The normal gland tissue is of a pale reddish colour, firm in texture, and forms a lobulated mass which is flattened anteroposteriorly and thicker in the centre than at the circumference. It consists of fifteen to twenty lobes, and these are composed of lobules, connected together by loose connective tissue, blood vessels and ducts. The smallest lobules, when fully developed, consist of a cluster of rounded alveoli which open into the smallest branches of the lactiferous ducts; these branches unite to form larger ducts which end in the terminal or *lactiferous ducts*, each of which drains a lobe of the gland. The lactiferous ducts hence also vary from fifteen to twenty in number; they converge towards the areola, beneath which they form variable dilatations, or *lactiferous sinuses*, which may serve as reservoirs for milk. (Some authorities, however, consider the lactiferous 'sinus' or dilatation to be a preparative artefact.) At the base of the papilla they contract, and pursue a straight course to its summit, ending as separate orifices considerably narrower than the ducts themselves. The ducts are surrounded by connective tissue containing longitudinal and transverse elastic fibres; they are lined by columnar epithelium and, outside these, a layer of longitudinally orientated myoepitheliocytes resting on a basal lamina. In the larger ducts the epithelium consists of two or more layers of cells, and near the openings on the papilla it becomes keratinizing stratified squamous in type. Mammary carcinoma is usually caused by neoplastic changes in the duct cells which form tumours within the ductular tissues, or infiltrate the surrounding connective tissue.

The mammary gland varies in its structure with *age* and during *pregnancy* and *lactation*. (The prenatal development of the gland is described on p. 156.) At *birth* it consists almost entirely of lactiferous ducts, no alveoli being present. This condition persists until puberty, only very slight branching of the ducts taking place, and the slight enlargement of the breast is due to deposition of fat and growth of the fibrous tissue stroma. After *puberty*, under the

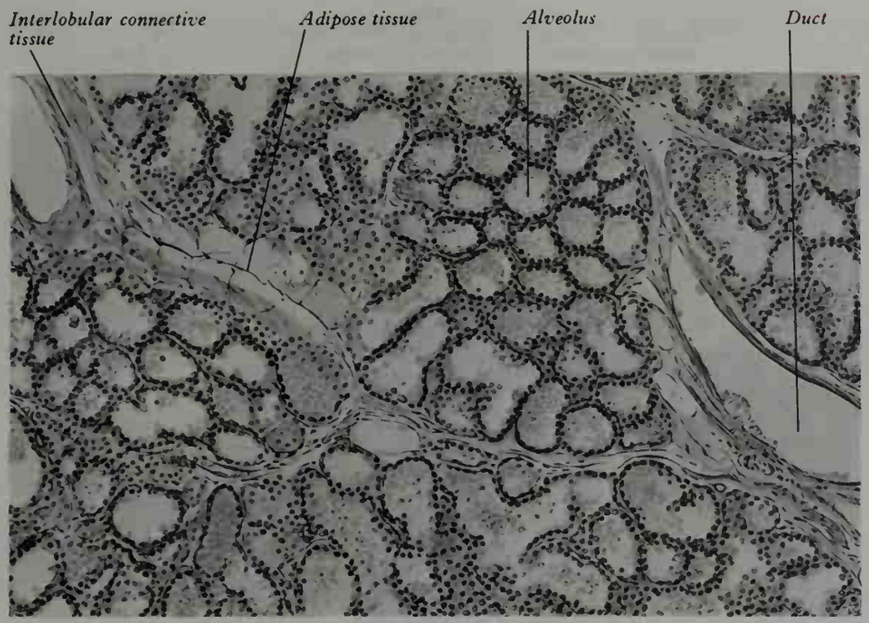
8.190 A dissection showing increased secretory lobules in the breast during lactation.

stimulating influence of ovarian oestrogenic hormones, the ducts develop branches and their ends form small, solid, spheroidal masses of granular polyhedral cells, which are potential alveoli. In the resting state the glandular epithelium is separated from the neighbouring vascularized stroma by a thin zone of fibroblasts amongst which vessels do not penetrate. This '*epithelio-stromal junction*' may exercise a control over the passage of materials to the secretory cells (Ozzello 1974). True secreting alveoli only appear during pregnancy, when the ducts branch markedly and their terminal parts develop lumina which increase in size as milk is secreted into them. This growth is due to the rising output of oestrogen and progesterone from the placenta. The amount of adipose tissue is also increased and there is a greater content of circulating blood. The secretory activity of the cells lining the alveoli increases progressively during the latter half of pregnancy. The secretion formed in the later stages of pregnancy and for a few days after parturition is known as *colostrum*. It contains cells, called *colostral corpuscles*, which have numerous fat globules in their cytoplasm. The nature of these cells is uncertain; some believing that they are the innermost cells lining the primitive alveoli, which undergo fatty degeneration and are shed into the alveolar lumen, whereas others maintain that they are macrophages which phagocytose the small amount of fat present in

8.191 Horizontal section of the breast at the level of the nipple in a multiparous female, aged forty years. (From Quain's *Anatomy*, vol. iii, part iv.)

the secretion at this time. True milk secretion commences a few days after parturition, due to the reduction in blood levels of oestrogen and progesterone, which appears to trigger off production of prolactin by the anterior lobe of the hypophysis (*see* Wolstenholme and Knight 1972, and p. 1439). The milk distends the alveoli, which are then lined by a single layer of granular, short columnar cells at the bases of which are stellate myoepitheliocytes lying on a basement membrane; the cells become flattened as the secretion increases in quantity. Fat droplets which accumulate in the superficial parts of the cells pass into the alveolar lumen.

The *alveolar cells* vary in their form and contents according to their activities in the secretory cycle of the mammary gland, being cuboidal in the resting state, and taller during lactation, although when the alveoli are distended with milk they may again become cuboidal because of the stretching of the alevolar lining; in the latter condition, however, they are much larger cells with huge secretory vacuoles distending their apices. Whilst secreting milk, their cytoplasm is somewhat basophilic and with the electron microscope is seen to contain copious amounts of granular endoplasmic reticulum, numerous mitochondria, lysosomes and free ribosomes. Apical to the nucleus, which is positioned in the more basal part of the cell, lies the Golgi complex and large secretory vacuoles of two types, proteinaceous and lipid containing. The protein vacuoles contain granules of casein in a micellar form, and other proteins of the milk; these are formed in the granular endoplasmic reticulum and passed to the Golgi apparatus where they are compounded into larger vacuoles and eventually secreted in a merocrine manner into the lumen of the gland. The lipid vacuoles do not apparently pass through the Golgi apparatus, but accumulate in the apical portion of the cell, often fusing to form large 'milk vacuoles' up to 10 μm across which frequently protrude from the surface of the cell before they are secreted. The lipid vacuoles are eventually discharged from the cell with a thin surrounding rim of cell membrane and cytoplasm (Pitelka 1977; Tobon and Salazar 1975; Saacke and Heald 1974; Hollmann 1974). This type of secretion may be considered as *apocrine* since actual cytoplasm is lost from the secreting cell, although not to the extent envisaged by those who first coined this term.



The alveolar cells are joined to each other apically by occluding tight junctions which prevent the passage of substances from the lumen of the gland into the intercellular spaces and *vice versa*; numerous desmosomes and communicating junctions also occur between cells (Pitelka *et al.* 1973).

In pregnant rats, one or two additional types of protein granule are synthesized, as precursors of the normal type of granule, and these may form part of the colostrum (Murad 1970).

The passage of the milk from the alveoli into and along the ducts is thought to be caused by the contraction of *myoepitheliocytes* (p. 39) sited between the lining cells and the basement membrane. The flow of milk is initiated by suckling, which stimulates the abundant nerves in the papilla and areola; these afferent impulses cause the formation of oxytocin by hypothalamic nuclei and its liberation into the circulation from the neurohypophysis, the oxytocin apparently stimulating contraction of the myoepitheliocytes and of the nonstriated muscle related to the ducts. In the absence of suckling, secretion of milk soon ceases. Oestrogenic hormones stimulate growth of the ducts whereas progesterone (produced by the the corpus luteum) directly or indirectly stimulates the formation of small alveoli at the ends of the ducts. The formation of true secretory alveoli in pregnancy is controlled by the synergic action of oestrogens, progesterone (produced mainly by the placenta), and hypophysial (pituitary) hormones (prolactin and growth hormone, which also maintain milk secretion). Commonly lactation is active for about five or six months after childbirth and then progressively diminishes, so that the infant is weaned at about nine months of age. When lactation ceases, the glandular tissue returns to a 'resting' condition, any milk remaining is absorbed and the alveoli shrink, many losing their lumen. In some cases the glandular tissue of the breast may not develop sufficiently during the whole of pregnancy to produce milk, whereas in others milk secretion may cease within a few weeks of the birth of the child. After the menopause, the mammary gland atrophies, the cellular elements of the alveoli and ducts degenerating and disappearing, though a few ducts may remain (Ozzello 1974). The connective tissue stroma becomes much less cellular and the collagenous fibres

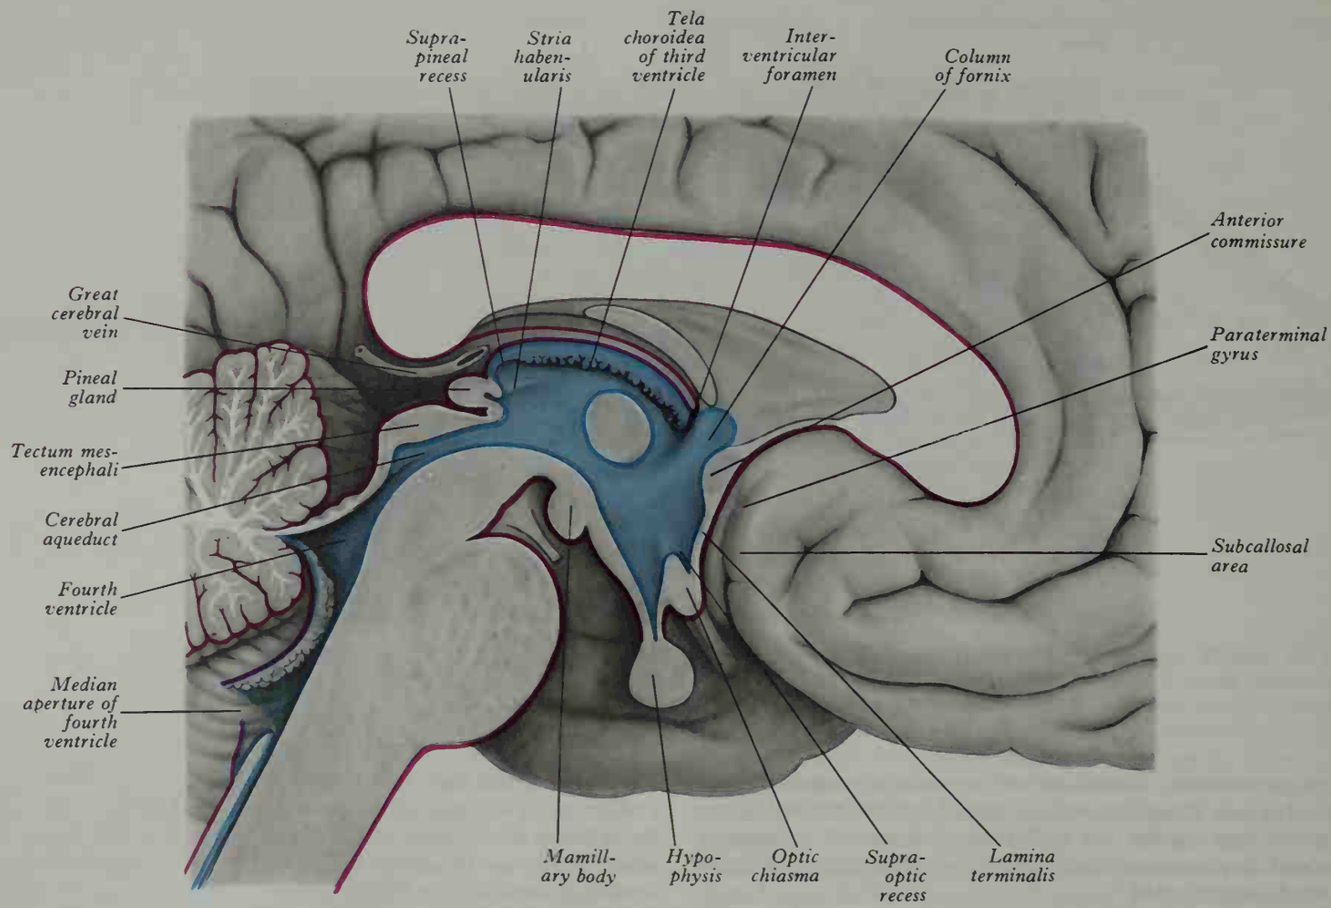
decrease in number. The amount of fat varies considerably.

In either sex, in the first week or two after birth, the cells lining the ducts may, under the influence of maternal oestrogenic hormones that have passed across the placenta, secrete a little fat-free fluid ('witch's milk').

Milk is a complex fluid, composed in the human of about 88 per cent water, 7 per cent lactose, 4 per cent fat and 1 per cent protein, as well as containing various ions, notably calcium, phosphate, sodium, potassium and chloride. Vitamins and antibodies mainly of the IgA (secretory) class are also present, the latter being largely responsible for the sterility of the milk during lactation (Jennesse 1974). The proteins are chiefly caseins and a lactalbumen; these, together with lactose and several of the triglycerides secreted in milk, are synthesized from various precursors entering the gland in the circulation, and are unique to the mammary gland. It should be added that the milk secreted initially, that is *colostral milk*, has a markedly different composition, being poor in nutrients and having an ionic composition rather similar to that of blood plasma. For a recent description of lactation and of the structure of the human breast *see* Larson (1978).

The male mamma is rudimentary throughout life and consists of small ducts (without alveoli), together with a little supporting adipose and fibrous tissue. Sometimes the ducts are largely represented by solid cellular cords. It may undergo a very slight, temporary enlargement at puberty. Generally the duct system does not extend beyond the limits of the areola, which is, however, well developed. The mammary papilla is relatively very small.

Vessels and nerves. The *arteries* supplying the mammary gland are derived from the thoracic branches of the axillary artery, and from the internal thoracic and intercostal arteries. The *veins* describe an anastomotic circle round the base of the nipple, the *circulus venosus*. From this circle and from the glandular tissue branches transmit the blood to the circumference of the gland, and end in the axillary and internal thoracic veins. The *lymph vessels* are described on p. 790. The *nerves* are derived from the anterior and lateral cutaneous branches of the fourth, fifth and sixth thoracic nerves. These nerves convey sympathetic fibres to the breast, but its secretory activities are largely under the control of hormones derived from the ovary and the hypophysis cerebri. The papilla is served by a dense nerve plexus supplying numerous sensory end organs such as Meissner's corpuscles and Merkel's discs, and also terminating in free nerve endings. This innervation is of great importance in signalling suckling (*vide supra*).



Applied Anatomy. The ducts descending from the papilla radiate through the gland, and incisions should hence be radial. A lactiferous duct may become obstructed and distended forming a cyst, or *galactocele*. Abscesses may occur between the septa, in the actual glandular tissue, subcutaneously near the papilla, or between the glandular tissue and the deep fascia on the anterior surface of pectoralis major.

Supernumerary mammae (polymastia) or papillae (polythelia) may occur in male or female, usually somewhere along a line which extends from the axilla to the pubic region. Occasionally the male mamma may undergo hypertrophy after puberty (gynaecomastia), a condition usually due to an imbalance between oestrogenic and androgenic hormones. (*See* pp. 1438, 1440, 1454, and 1461 for mammary endocrine influences.)

THE ENDOCRINE SYSTEM

For a multicellular organism to survive and maintain its integrity in a variable and often adverse environment, regulatory mechanisms are essential. The metazoa have attained a measure of functional freedom from the vagaries of their external environment (over which only the most advanced have much control and this only of a short-term nature) by developing the capacity to regulate, with varying degrees of success, the composition and properties of the immediate surroundings of the majority of their cells. These surroundings comprise the intercellular or tissue fluid, and, in those metazoa with a vascular system, the fluid component of the blood and lymph. The effectiveness with which the stability of these media is maintained is directly related to the success and longevity of the organism.

Tissue fluid and plasma are maintained in a stable state through the co-ordinated regulatory activity of the autonomic division of the nervous system and the endocrine system, the latter being subdivided into the diffuse neuro-endocrine system (p. 1454) and the endocrine system proper. All operate through intercellular communication, but differ in the manner and speed of this communication, and in the degree of localization of the effects

8.194 Part of a median section through the brain to demonstrate the location of the hypophysis and its immediate surroundings, particularly hypothalamic structures. Cut edge of pia mater shown in red, ependyma in blue. Compare with fig. 7.110A and B.

which they produce. The *autonomic system* utilizes neural impulse transmission and neurotransmitter release to transmit information, is swift in action and localized in the responses which it induces; the diffuse *neuro-endocrine system* makes use of secretions only, is slower in action, and the responses which it induces are less localized, for the secretions can act on contiguous cells in the manner of neurotransmitters, on groups of nearby cells which they reach by diffusion in the manner of a paracrine secretion, or on distant cells which they reach by way of the blood in the manner of a hormone; the *endocrine system* proper, comprising those isolated cells, clusters of cells, and discrete ductless glands which produce hormones, organic molecules which are transported in the blood to distant effector cells, is still slower in action and even less localized, though the effects which it produces are specific to certain cell types and of longer duration. The regulatory systems described above are not mutually exclusive but overlap in form and function. There is a gradation from the neural autonomic system, through the intermediate diffuse neuro-endocrine system, to the hormonal endocrine system proper.

That the autonomic and endocrine systems are closely interrelated both structurally and functionally becomes apparent when the hypothalamus is considered (p. 970). This acts as an integrating centre for both systems, and is the major site at which their activities combine. As well as its classic nervous functions, it also operates as an endocrine organ, producing by neurosecretion a wide variety of peptide hormones including releasing and release-inhibiting factors which control the activity of the adenohypophysis, a major endocrine gland itself. Although conventionally considered separately, the autonomic system, diffuse neuro-endocrine and endocrine system proper, collectively represent a single neuro-endocrine regulatory system which operates in a co-ordinated manner to control the metabolic activities and internal environment of the organism, providing conditions in which it can function in a biologically successful manner.

There are, in addition to the discrete endocrine glands and diffuse neuro-endocrine system described in the following section, other hormone-producing cells forming minor components of other systems of the body and described with those systems. These include the pancreatic islets (p. 1371), the gastro-entero-endocrine cells (p. 1364), certain cells of the thymus (p. 780) and kidney (p. 1396), endocrine cells of the lung (p. 1259), the interstitial cells of the testis (p. 1415), and the interstitial, follicular, ovarian and luteal cells of the ovary (p. 1424). During pregnancy the placenta (p. 135) is also a major endocrine organ.

The Hypophysis Cerebri

The hypophysis cerebri (pituitary gland; **8**.194–198) is a reddish-grey and somewhat ovoid body, measuring about 12 mm in transverse and 8 mm in anteroposterior diameter. It weighs about 500 mg. It is continuous with the apex of the infundibulum, a hollow conical projection from the inferior aspect of the tuber cinereum (p. 966). The gland lies in the hypophysial fossa of the sphenoid bone, where it is overlapped by a circular fold of dura mater, the *diaphragma sellae*; this fold has a small central aperture through which the infundibulum passes, and it separates the anterior part of the superior surface of the hypophysis from the optic chiasma (**8**.195). On each side, the hypophysis is related to the cavernous sinus and the structures which it contains (p. 746). Inferiorly, it is separated from the floor of the fossa by a large, partially loculated, venous sinus, which communicates with the circular sinus (p. 748). The meninges blend with the capsule of the hypophysis and cannot be identified as separate layers in the fossa.

The terminology of the divisions and subdivisions of the hypophysis cerebri is still somewhat confused. There is, however, a basic division into two regions of different embryological, morphological and functional characteristics. One is a downgrowth from the diencephalon connected by neural pathways with the hypothalamus, the other is a derivative of the ectodermal roof of the stomatodeum. These are named respectively the *neurohypophysis* and *adenohypophysis*. Both include parts of the *infundibulum* or hypophysial stalk, and in this differ from the older terms—anterior and posterior lobes, which do not include the stalk. The infundibulum itself consists of a neural core, the *infundibular stem*, which contains the neural connexions of the hypophysis, and this in turn is continuous with the *median eminence* of the tuber cinereum (p. 966). Thus, the *neurohypophysis* is commonly, but not invariably, taken to include the median eminence, the infundibular stem, and the main posterior part of the hypophysis—the *neural lobe* or *pars posterior*. The macroscopic infundibulum also comprises an extension of the adenohypophysis, which largely surrounds most of the neural infundibular stem; this is the *pars tuberalis* or *infundibularis*. The major region of the adenohypophysis is divisible into a *pars anterior* (pars distalis) and a *pars intermedia*, separated in fetal and early post-natal life by the hypophysial cleft, a vestige of the cavity of the ectodermal diverticulum, Rathke's pouch (p. 199), from which the adenohypophysis develops. This cleft usually becomes obliterated in childhood, persisting only as a variable series of cystic cavities scattered near the adeno-neurohypophysial interface and sometimes invading the neural lobe. The pars intermedia is, in any case, rudimentary in mankind, and because it may also be partially displaced into the neural lobe it has been included in both the pars anterior and pars posterior by different authorities. Apart from this terminological equivocation, which is of little significance in the human hypophysis, in view of the exiguous status of the pars intermedia, the pars anterior and pars posterior (or nervosa) may be equated with the terms anterior and posterior lobes. When the associated parts of the infundibulum which are continuous with these two lobes are considered with them, the names adenohypophysis and neurohypophysis become appropriate usage. To recapitulate therefore, in the present account the following terms are used:

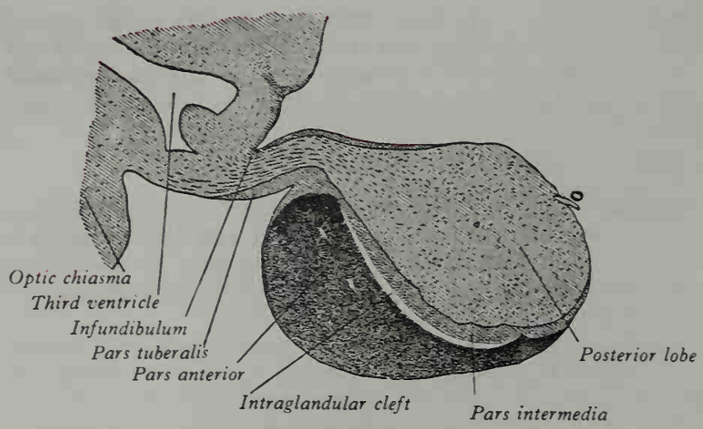
(1) The *neurohypophysis* includes the pars posterior (pars nervosa, posterior, or neural lobe), the infundibular stem and the median eminence.

(2) The *adenohypophysis* includes the pars anterior (pars distalis or glandularis) and the pars intermedia, together with the pars tuberalis.

The various subdivisions of the hypophysis cerebri are shown in **8**.195, 196A, 198. They differ considerably in the type of cells, their arrangement, and in the details of their vascular and neural supplies, and these features have engendered a formidable literature, which can only be represented here briefly and simply.

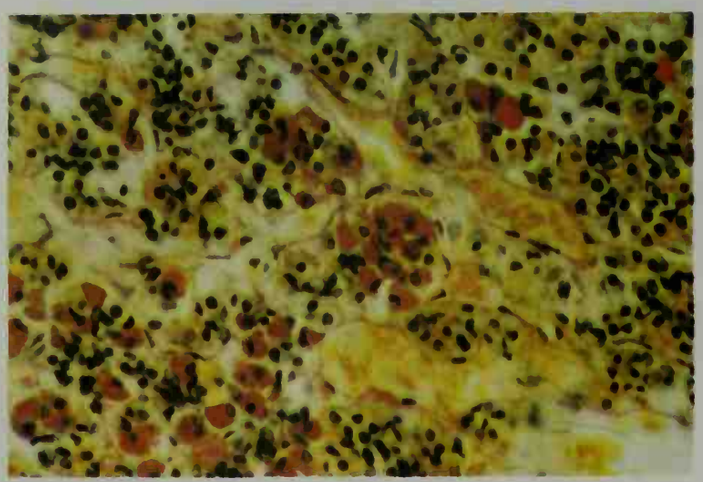
THE ADENOHYPOPHYSIS

The adenohypophysis (**8**.196, 197) is a highly vascular structure, consisting of epithelial cells of varying size and shape arranged in cords, irregular masses or follicles, separated by thin-walled vascular sinusoids and supported by a complex network of reticular tissue.



It is known from numerous experimental and clinical investigations that at least seven distinct hormones are synthesized and released from the adenohypophysis, most of them being *tropic hormones* such as *somatotropin* (STH) which is involved in the control of body growth to maturity; *mammotropin* or *lactogenic hormone* (LTH) which stimulates the growth and secretory activity of the female mammae during pregnancy; *adrenocorticotropin* (ACTH) which governs the secretion of some of the hormones by the adrenal cortex; *thyrotropin* (TSH) which stimulates thyroid activity; *follicle-stimulating hormone* (FSH) which stimulates growth of ovarian follicles and their secretion of oestrogens in the female, and spermatogenesis in the male; *interstitial-cell-stimulating hormone* (ICSH) which activates androgen secretion by the Leydig cells of the testis and progesterone secretion by the corpus luteum (then termed luteinizing hormone, LH); and finally *melanocyte-stimulating hormone* (MSH) which causes an increase in cutaneous pigmentation. Most of these hormones also have many other complex metabolic effects which are, however, beyond the scope of the present account.

CELL TYPES OF THE ADENOHYPOPHYSIS



The problem of the cellular sites of secretion of the adenohypophysial hormones has attracted much study. A wide variety of methods have been developed to distinguish between different cell types by their staining reactions (Harris and Donovan 1966); the earlier techniques used the simple criterion of the differential binding affinities of the cells for mixtures of acidic and basic dyes; an example of the former is orange-G and of the latter, aldehyde fuchsin. Those cells which stained strongly were termed *chromophilic cells*, those showing little affinity for dyes, *chromophobic cells*. Of the chromophilic cells, those which bound acidic dyes were classed as *acidophils* (α-cells), in contrast to the *basophils* (β-cells) which stained strongly with basic dyes.

8.196B A medium-power micrograph of adenohypophysial cells stained with the PAS-orange G technique, to distinguish between α-cells (yellow), β-cells (red to brown) and chromophobic cells (pale grey with little cytoplasm). A number of large vascular sinusoids containing yellow-stained erythrocytes are also prominent. Magnification × 400.

8.196C A high-power micrograph of a group of cells stained as for B, grouped around a vascular sinusoid. Note α-cells (yellow) and β-cells (red). Magnification × 1,000.

Modifications of such techniques using complex, multi-stage staining methods, further distinguished many sub-categories of cells, each with its own tinctorial nuance. These techniques, applied particularly to experimental or pathological pituitary glands from individuals with known hormonal defects, were used to correlate specific cell types with specific hormones. However, many uncertainties prevailed, because of the difficulty in the standardization of stains, and the further difficulty of classifying the endless minor variations in different individuals and species.

More recently, the methods of immunochemistry have been brought to bear on this problem (Nakane 1970), and it has been possible by immunofluorescence techniques to identify the site of synthesis of individual hormones with some certainty. Such methods, combined with ultrastructural and cell fractionation studies, have clarified the problem considerably although some difficulties still remain. At the present time all of the major hormones have been assigned to particular cell types; the terminology stemming from the older schemes of classification has, however, been generally retained, and the cells will be described briefly here. Ultrastructural studies of the normal human adenohypophysis are rare, and much of the information available on the fine structure of the cells of the adenohypophysis has been obtained, of necessity, from studies on non-human primates. In the following description the cytological details given refer, unless otherwise stated, to the adenohypophysis of the Rhesus monkey (Costoff 1977).

The pars anterior contains the following cell varieties:

A. *The chromophil cells*

1. *Acidophils (α cells)*

(*a*) *Somatotrophs*. Usually arranged in groups along the sinusoids, these ovoid cells are the largest and the most abundant of the adenohypophysial acidophils. They secrete proteinaceous STH (GH) and their distinguishing stain is orange G. They contain large numbers of electron-dense, spherical, secretory granules of 350 to 500 nm diameter, and have a well-developed Golgi complex although the granular endoplasmic reticulum is not particularly extensive. Cells with a single cilium have been observed. Cells having a similar fine structure have been found to characterisize human eosinophilic adenomata (Zambrano *et al.* 1968).

(*b*) *Mammotrophs*. These secrete the proteinaceous hormone prolactin, and are the dominant cell type during pregnancy. They hypertrophy during lactation. Their distinguishing stain is erythrosin but they also have an affinity for azocarmine. Their secretory granules, which are the largest of any hypophysial cell type (600 to 1000 nm in diameter), are evenly dense and either ovoid or irregular, the latter type resulting from the fusion of the former. Excess granules fuse with lysosomes to form autophagic vacuoles within which they are degraded by hydrolytic enzymes. In active cells the granular endoplasmic reticulum and Golgi complex are both well-developed. Mammotrophs are present in the adenohypophyses of males as well as females but have more abundant secretory granules in the latter.

(*c*) *Corticotrophs*. These secrete ACTH. They are small cells, grouped in clusters, often arranged as follicles around central masses of glycoprotein (von Lawzewitsch *et al.* 1972) and stain faintly with periodic acid/Schiff. They are irregularly stellate in shape and their sparse secretory granules, some 200 to 250 nm in diameter, are generally located immediately beneath the plasma membrane. The characteristic shape of the cells and the peripheral location of the secretory granules are useful aids to the identification of corticotrophs (Siperstein and Miller 1970). The granular endoplasmic reticulum is of a scattered vesicular or short lamellar type and the Golgi complex is somewhat small. Although classified here as α-cells, some authorities have placed the corticotrophs in the β-cell category (Baker *et al.* 1970). It is possible that their staining characteristics and hence their classification may vary with their metabolic state. The smallness and sparseness of their secretory granules, together with their poor staining properties, have frequently led to the classification of corticotrophs as chromophobes.

2. *Basophils (β cells)*

(*a*) *Thyrotrophs* (Beta-basophils). These secrete TSH. They are elongate polygonal cells arranged in clusters towards the centre of the adenohypophysis. They are usually found deep within the cell cords and are thus not in direct contact with the sinusoids. They are stained selectively by aldehyde fuchsin. Their peripherally arranged granules are irregular in shape and are less electron-dense than those of other types of basophil; being only 100 to 150 nm in diameter, they are among the smallest granules found in the cells of the adenohypophysis.

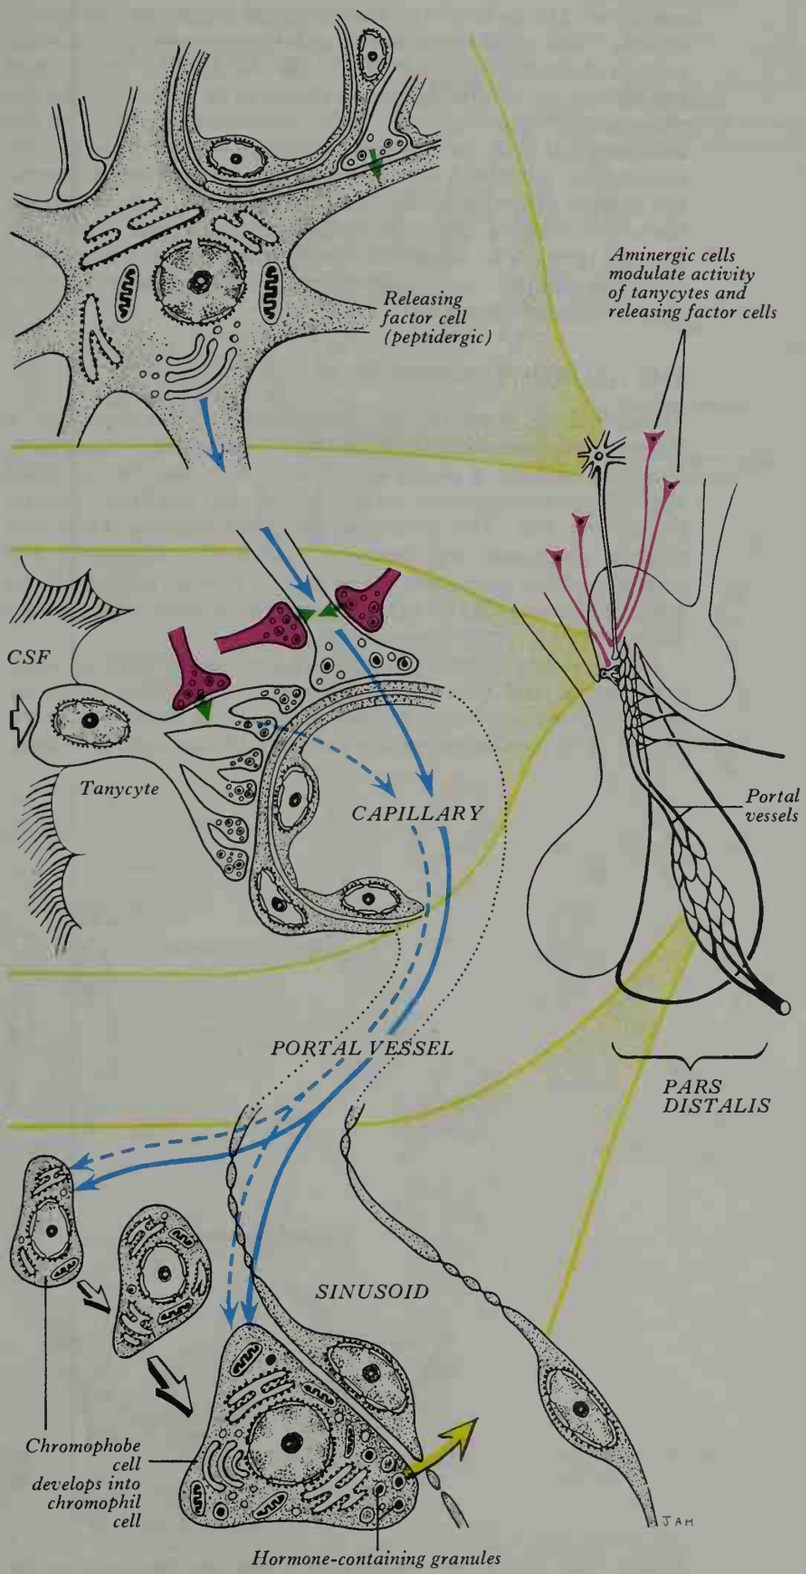
(*b*) *Gonadotrophs (Delta-basophils)*. These are larger than the

thyrotrophs, are round in shape, and usually lie next to the sinusoids. Their secretory granules have an affinity for periodic acid/Schiff. In some cells, usually peripheral in position, the granules stain purple, while in others, more centrally placed, they stain red, and it has been suggested that the former secrete FSH and the latter LH or ICSH (Purves 1961). Ultrastructural studies of the rat adenohypophysis have also distinguished two separate cell types (Kurosumi and Oota 1968). However, immunocytochemical studies of Phifer *et al.* (1973) in man and of Moriarity (1975) in the rat suggest that FSH and LH may be present simultaneously in the same cell. Gonadotrophs have pleomorphic nuclei. Their spherical granules are from 200 to 300 nm in diameter, their granular endoplasmic reticulum is vesicular and the Golgi complex well-developed. Gonadotrophs similar to those of the Rhesus monkey have been described in man (von Lawzewitsch *et al.* 1972).

B. *The chromophobe cells*

Chromophobe cells are present as inconspicuous clusters of small elements with scanty cytoplasm, and an ultrastructural appearance suggestive of metabolic inactivity. They may represent a non-secretory phase in the activity of other glandular cell types.

Variations occur in the distribution of these diverse cell types in the adenohypophysis. Generally, similar cells occur in groups, probably reflecting their pattern of development.



The pars intermedia contains numerous β-cells, and chromophobe cell-follicles surrounding PAS-positive colloidal material. Some of these are pouches derived from the embryonic intrahypophysial cleft (i.e. the cavity of the pouch of Rathke). In some species in which this cavity remains large in the fully developed gland, a ciliated lining epithelium has been described.

The secretory cells of the pars intermedia contain granules containing either α-endorphin or β-endorphin scattered uniformly throughout their cytoplasm (Bloom *et al.* 1977; Guilleman 1978). These same cells have also been shown by numerous investigators to contain a variety of peptide hormones including ACTH and α-MSH (melanocyte stimulating hormone). They are considered to belong to the APUD series of cells (p. 1454), as are the other secretory cells of the adenohypophysis. Endorphin has also been found in the pars anterior, but here it is localised to peripherally placed granules in discrete groups of cells.

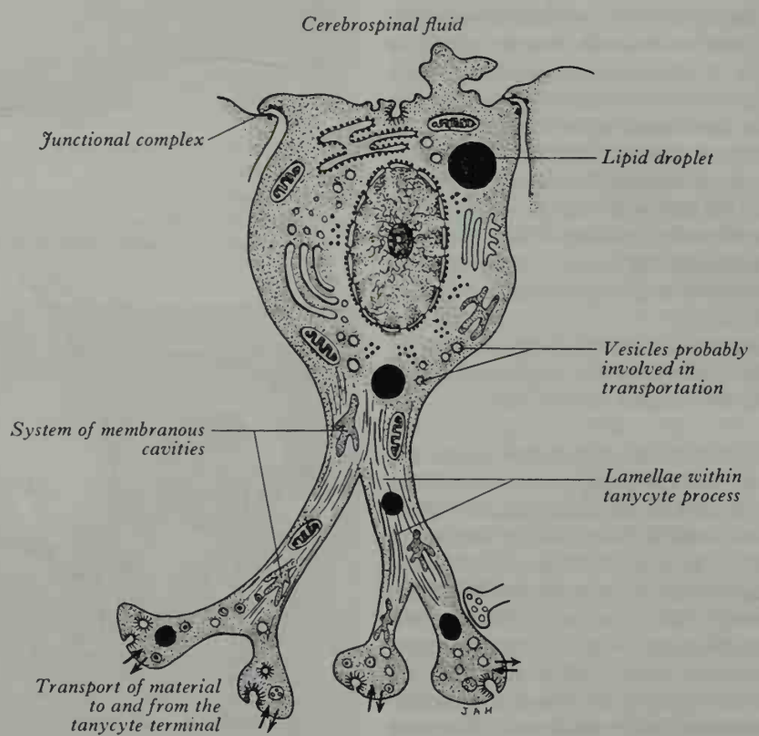
The pars tuberalis is characterized by the large number of blood vessels traversing it. Between these are cords or balls of undifferentiated cells admixed with some α- and β-cells.

The secretion of adenohypophysial hormones into the circulation appears to occur by the exocytosis of the vesicular contents into the perivascular spaces of the sinusoids, the latter being lined with a fenestrated endothelium which facilitates diffusion into the bloodstream. The signal for secretion is the liberation of chemical releasing factors from neurons (McKelvy 1974) in the median eminence, the nucleus infundibularis (arcuate nucleus), and other hypothalamic centres, into the upper radicles of the portal system of veins which carries them to, and distributes them within, the adenohypophysis. These neurosecretory cells are effectively *neuroendocrine transducers* (Wurtman 1970), in that they receive neural signals and respond to them by secreting hormones; they thus convert one type of signal into another. The neurons producing releasing factors are peptidergic, while the neurons which modulate their activity are largely monoaminergic and make either axosomatic or axo-axonic synapses with them.

Tanycytes (p. 836, **8**.197A and B) may also be involved in secretion control, possibly transporting hormones from the cerebrospinal fluid to the capillaries of the portal system (Knigge 1976) and/or from hypothalamic neurons to the cerebrospinal fluid (Joseph and Knigge 1978). The presence of tight junctions between them and neighbouring ependymal cells (Brightman *et al.* 1975), although of a somewhat rudimentary nature compared, say, with those of the choroid plexus, impedes the movement of peptides and even of some amino acids (Weindl and Joynt 1972),

8.197A A diagram illustrating the control systems which influence the hormonal output of the adenohypophysis. The small diagram on the right shows the ventral hypothalamus, median eminence, and adenohypophysis (pars distalis), and their associated neurons and vasculature. On the left three zones are shown in greater detail. The concatenation of events is as follows: under the influence of blood-borne factors and neural stimuli, the hypothalamic neuron shown above liberates specific releasing factors into capillaries of the median eminence. Modulation at this point is mediated by aminergic neurons and tanycytes. Onward transport of these factors through portal vessels is indicated by blue arrows. Stimulation and hormone production and release on the part of the adenohypophysial cell are indicated.

and suggests that materials such as releasing factors would have to pass across the ependyma through, rather than between, the tanycytes. The endocytotic (and presumably also the exocytotic) activity of tanycytes appears to be under monoaminergic neuronal control (Kobayashi 1975; Nozaki *et al.* 1975). The tanycytes of the walls of the ventricular recess appear to be well suited for the transport of releasing factors from neurosecretory cells to the cerebrospinal fluid, for they course through the bed of the arcuate nucleus and are linked to its neurons by junctions which permit the passage of low molecular weight substances such as peptide hormones between the cells which they unite (del Cerro and Knigge 1977). The suggested involvement of the tanycytes in secretion control by transporting releasing factors awaits experimental verification.



THE NEUROHYPOPHYSIS

The posterior lobe of the hypophysis is developed as a downgrowth from the floor of the diencephalon, and during early fetal life contains a cavity continuous with that of the third ventricle. In some animals, for example the cat, this cavity persists throughout life. The posterior lobe, infundibular stem and median eminence are frequently termed collectively the *neurohypophysis (vide supra)*. (For general reviews consult Harris 1955; Heller and Clark 1962; Scharrer and Scharrer 1963; Gabe 1966; Donovan 1970; Knowles 1974.)

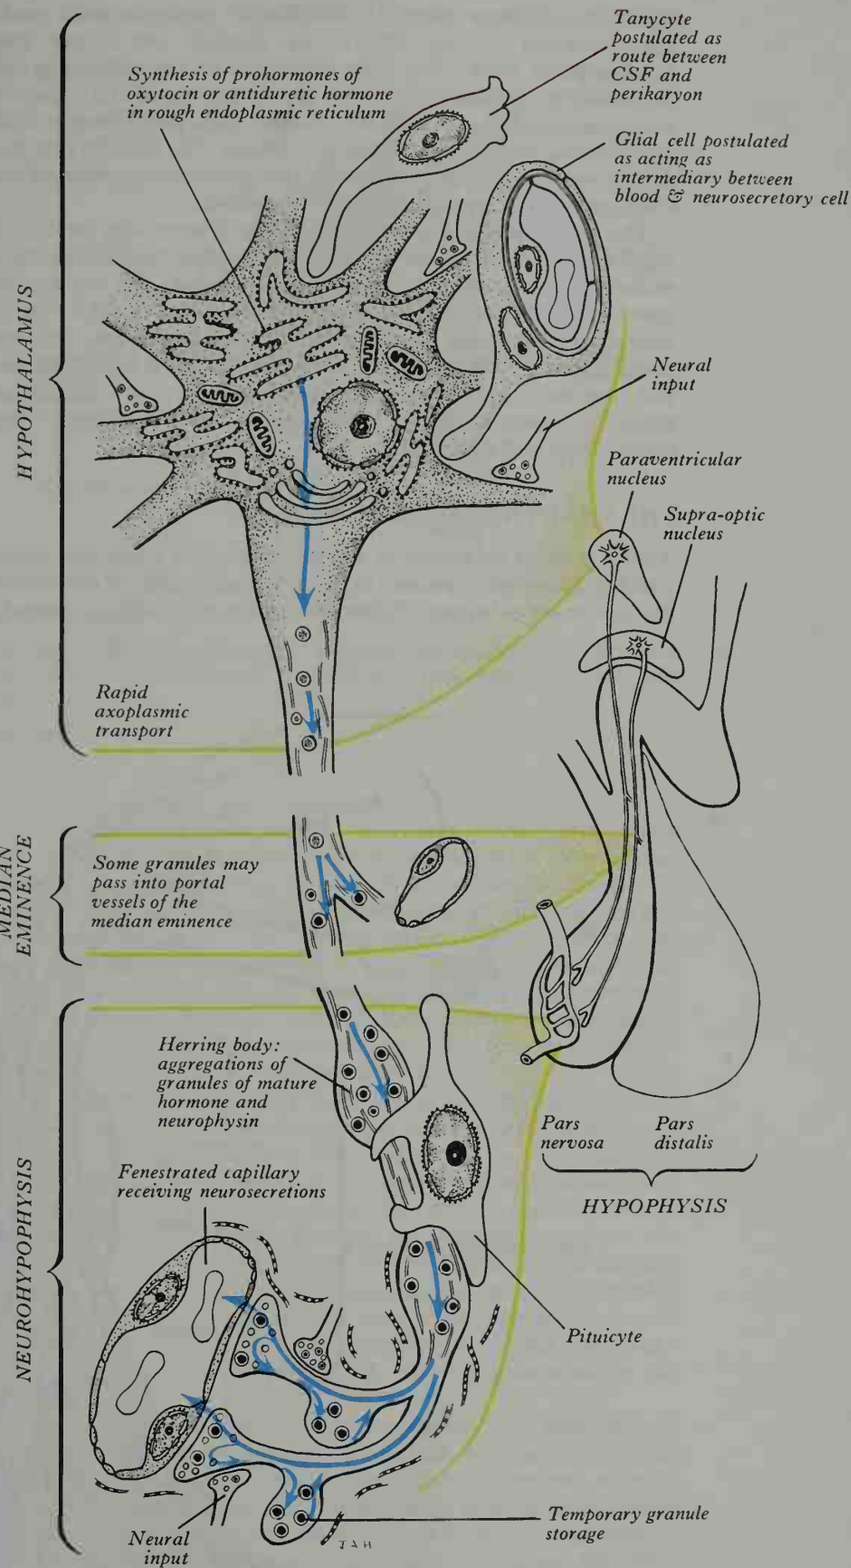
Axons stemming from perikarya situated in the hypothalamus (supra-optic and paraventricular nuclei, and other sites) are present in the neurohypophysis; some of the fibres are short, ending in the median eminence and infundibular stem in relation to the superior capillary beds of the venous portal circulation, and thus providing the possibility of neural control of adenohypophysial function (*vide infra*). Longer axons from these nuclei pass to the main mass of the neurohypophysis, where they terminate in relation to the vascular sinusoids. These nerve fibres constitute the neurosecretory hypothalamohypophysial tract, which is considered in greater detail elsewhere (p. 969). The chief hormones concerned are vasopressin (antidiuretic hormone, ADH) which controls the reabsorption of water by the kidney tubules, and oxytocin, which promotes the contraction of uterine and mammary nonstriated muscle. The site of production of these hormones has been described (p. 1439); they are passed from the perikarya along the axons of the tract, and are finally released at the nerve terminals. Ligation of the tract causes a proximal damming of the secretion granules, which can be stained, by virtue of their high glycoprotein content, by the PAS technique. The active hormones are simple polypeptides, but they are elaborated and transported within the cell with a glycoprotein, *neurophysin*. When released into the circulation the association between the two is broken, and the hormone is then carried by plasma glycoproteins to its target sites.

Histologically, the neurohypophysis is composed of thin, non-myelinated nerve fibres and associated cells, which are the terminal ramifications of the hypothalamohypophysial tract. Proximally, in the infundibulum, the fibres are ensheathed by typical astrocytes, but towards the posterior lobe another type of cell, the *pituicyte*, makes its appearance. The latter is a dendritic cell with variable appearance, but often possessing long processes which lie parallel to the adjacent axons, and which form the bulk of the non-excitable tissue of the neurohypophysis. The cytoplasmic processes of many pituicytes terminate on or near the surfaces of neighbouring capillaries and sinusoids between terminations of nerve fibres. The latter end in the perivascular spaces, and, although they approach the wall of the sinusoid fairly closely, they remain separated from it by two basal laminae, one applied to the nerve ending, the other to the surface of the endothelial cells. Some fine collagen fibres are also often interposed between the two. In regions other than the perinuclear zone the cytoplasm of the endothelial cells is extremely attenuated, and presents regular fenestrations (**8**.197C).

Three distinct types of nerve terminals have been described in the posterior lobe. These are: (1) terminal axonal swellings lying adjacent to the vascular sinusoids, which contain large (200–300 nm) dense vesicles, characterized biochemically as containing hormones bound to glycoproteins; they also contain clear, small (40–60 nm) spherical vesicles; (2) peri-axonal endings containing small (80 nm) dense-cored vesicles, similar to catecholamine-containing vesicles found in sympathetic nerve fibre endings (p. 775); (3) peri-axonal endings containing small (40–60 nm) clear spherical vesicles; the latter form synapses with the large hormone-containing endings (Bargmann 1966). The interactions between these various nerve terminals is not entirely clear. The

8.197B The general ultrastructure of a tanycyte. (See text on pp. 836 and 1441 for explanatory details.)

hormones appear to be released by exocytosis from the endings containing large dense vesicles. It is possible that excitation or inhibition of release is mediated by the other types of endings, or possibly by the excitation of the hormone-containing endings themselves.



THE VESSELS OF THE HYPOPHYSIS

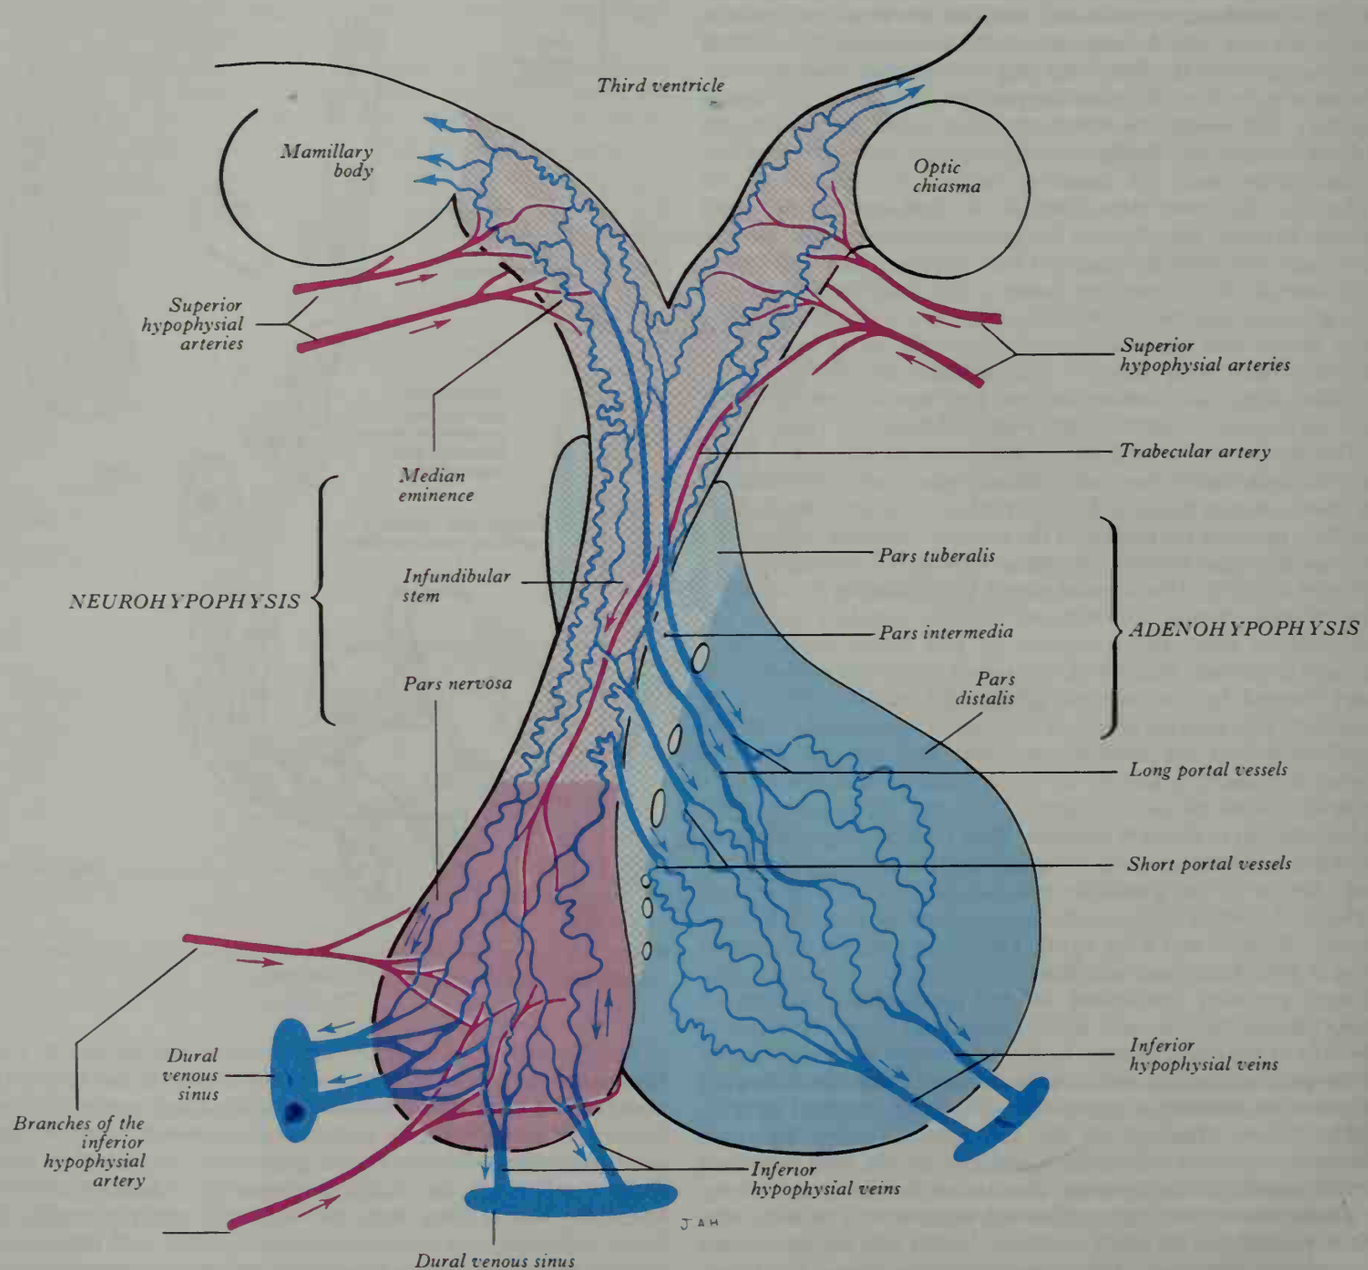
These have been studied in preparations injected with neoprene latex or with the dye Berlin blue, and also by certain techniques which stain erythrocytes (Popa and Fielding 1930 *a*, *b*; Green and Harris 1949; Xuereb *et al.* 1954 *a*, *b*; Stanfield 1960). More recently, scanning electron microscopy has been used to examine corrosion casts in attempts to determine the details of the angio-architecture of the median eminence and the vascular relationships within and between the neurohypophysis and the adenohypophysis (Page and Bergland 1977).

The arteries of the pituitary gland stem from branches of the internal carotid artery, a single *inferior* and a series of *superior hypophysial arteries* on each side. The inferior hypophysial artery arises from the cavernous portion of the internal carotid artery, while the superior hypophysial arteries arise from its supraclinoid portion and from the anterior and posterior cerebral arteries. Each inferior hypophysial artery divides into medial and lateral branches which anastomose with their fellows from the opposite side forming an *arterial ring* around the infundibular process of the neurohypophysis. From this ring several small branches pass centrally to supply the neurohypophysis, breaking up into a capillary bed within its substance. The superior hypophysial arteries supply the median eminence, the upper part of the infundibulum and, via branches termed the *arteries of the trabeculae*, the lower infundibulum. A confluent capillary bed extends through the whole of the neurohypophysis (the median eminence, infundibular stem and pars nervosa), and is supplied with arterial blood from two sources, the inferior hypophysial arteries below and the superior hypophysial arteries above. It has been shown that *reversal* of blood flow can occur in cerebral capillary beds lying between two sources of arterial supply (Gillilan 1974), and similar reversal has been suggested in the neurohypophysial capillary bed (Page and Bergland 1977).

The arteries of the median eminence and the upper and lower parts of the infundibulum end in characteristic tufts of capillaries, the most complex being in the upper infundibulum. Two distinct capillary plexuses are present in the median eminence: an *external* or *'mantle' plexus* (Green 1951) and an *internal* or *'deep' plexus* (Duvernoy 1972). The external plexus is supplied by the superior hypophysial arteries, is continuous with the capillary bed of the infundibular stem, and is drained by *long portal vessels* which descend to the pars anterior. The internal plexus projects into the bowl formed by the external plexus, by whose vessels it is supplied. The internal plexus is continuous posteriorly with the capillary bed of the infundibular stem and, like the external plexus, is drained by *long portal vessels* which descend to the pars anterior. *Short portal vessels* run from the lower part of the infundibulum to the pars anterior. Both varieties of portal vessel open into vascular sinusoids lying between the secretory cell cords and clumps of the glandular part of the pituitary, providing virtually the whole of its vascular supply; there is no direct arterial supply (Wislocki and King 1936). The *portal system* is considered to be of great functional significance, carrying hormone-releasing factors, probably elaborated in the parvocellular groups of hypothalamic neurons and which control the secretory cycles of the cells of the pars anterior. Little is known of the blood supply of the pars intermedia, which appears to be avascular according to corrosion casts of the hypophysis (Page and Bergland 1977).

The venous drainage of the neurohypophysis is by three potential routes: to the adenohypophysis via the long and short portal vessels, to the systemic circulation via the large inferior hypophysial veins which open into the dural venous sinuses, or to the hypothalamus via small capillaries which pass between it and the median eminence. The venous drainage allows the hypophysial hormones to leave the gland and be carried to their target organs. It also facilitates the feedback control of secretion. In contrast to the rich venous drainage of the neurohypophysis, that of the adenohypophysis appears to be somewhat restricted. Few veins connect it with the surrounding systemic venous structures directly, and this raises the question of the route by which blood leaves it. If flow in the short portal system between the adeno- and neurohypophysis were reversible (Adams *et al.* 1969), then these vessels could act as drainage channels. Adenohypophysial hormones would pass into the neurohypophysial capillaries before entering the systemic venous system and this would provide the 'short feedback' loop which has been postulated on the basis of endocrinological investigation. Reversed flow within the neurohypophysial capillary bed (from the neurohypophysis to the hypothalamus (Tôrök 1954) would provide a vascular route

8.197C A diagram summarizing the control systems which influence the production of neurohypophysial hormones.



by which hormones released in the neurohypophysis could reach the tanycytes of the ventricular surface and hence the cerebrospinal fluid. The demonstration of neurohypophysial hormones in this fluid (Robinson and Zimmerman 1973) and of releasing factors both here and in the tanycytes (Knigge and Joseph 1974) adds weight to this hypothesis. The concept that the neurohypophysis secretes into the third ventricle, proposed by Cushing in 1912, may yet prove to be correct.

The implications of recent advances in determining the blood supply of the pituitary are far-reaching. Rather than the median eminence acting as the final common pathway for the neural control of the adenohypophysis (Harris 1947), the entire neurohypophysis may be involved; its capillary bed may actively and selectively 'determine the destination of both hypothalamic and pituitary secretions, conveying some to the glandular pituitary, others to distant target organs, and yet others to the brain' (Page and Bergland 1977).

THE PHARYNGEAL HYPOPHYSIS

This is a small collection of adenohypophysial glandular tissue which is consistently present in the mucoperiosteum of the roof of the nasopharynx in man (Boyd 1956) and in many other mammals (McGrath 1974). By 28 weeks of human intrauterine development, it is capable of hormone secretion and is richly vascularized, receiving its blood supply from the systemic vessels of the roof of the nasopharynx. At this stage it is covered posteriorly by fibrous tissue, but in the second half of fetal life this is replaced by numerous venous sinuses and an extended trans-sphenoidal portal venous system develops, bringing it under the same hypothalamic control as the cranial adenohypophysial tissue (McGrath 1978). The peripheral vascularity of the pharyngeal hypophysis persists until about the fifth year, after which it becomes re-invested in fibrous tissue and is presumed to be again under the control of factors carried in the systemic blood.

Although in the male the pharyngeal hypophysis does not change in size significantly after birth, in the female it becomes temporarily smaller, returning to its volume at birth during the fifth decade (McGrath 1971), when once again its control may be through factors carried in the trans-sphenoidal extension of the hypothalamo-hypophysial portal venous system. It has been suggested that the human pharyngeal hypophysis may provide a reserve of potentially functional adenohypophysial tissue which may be stimulated, particularly in the female, to synthesize and secrete adenohypophysial hormones in middle age when the intra-cranial adenohypophysial tissue is beginning to fail.

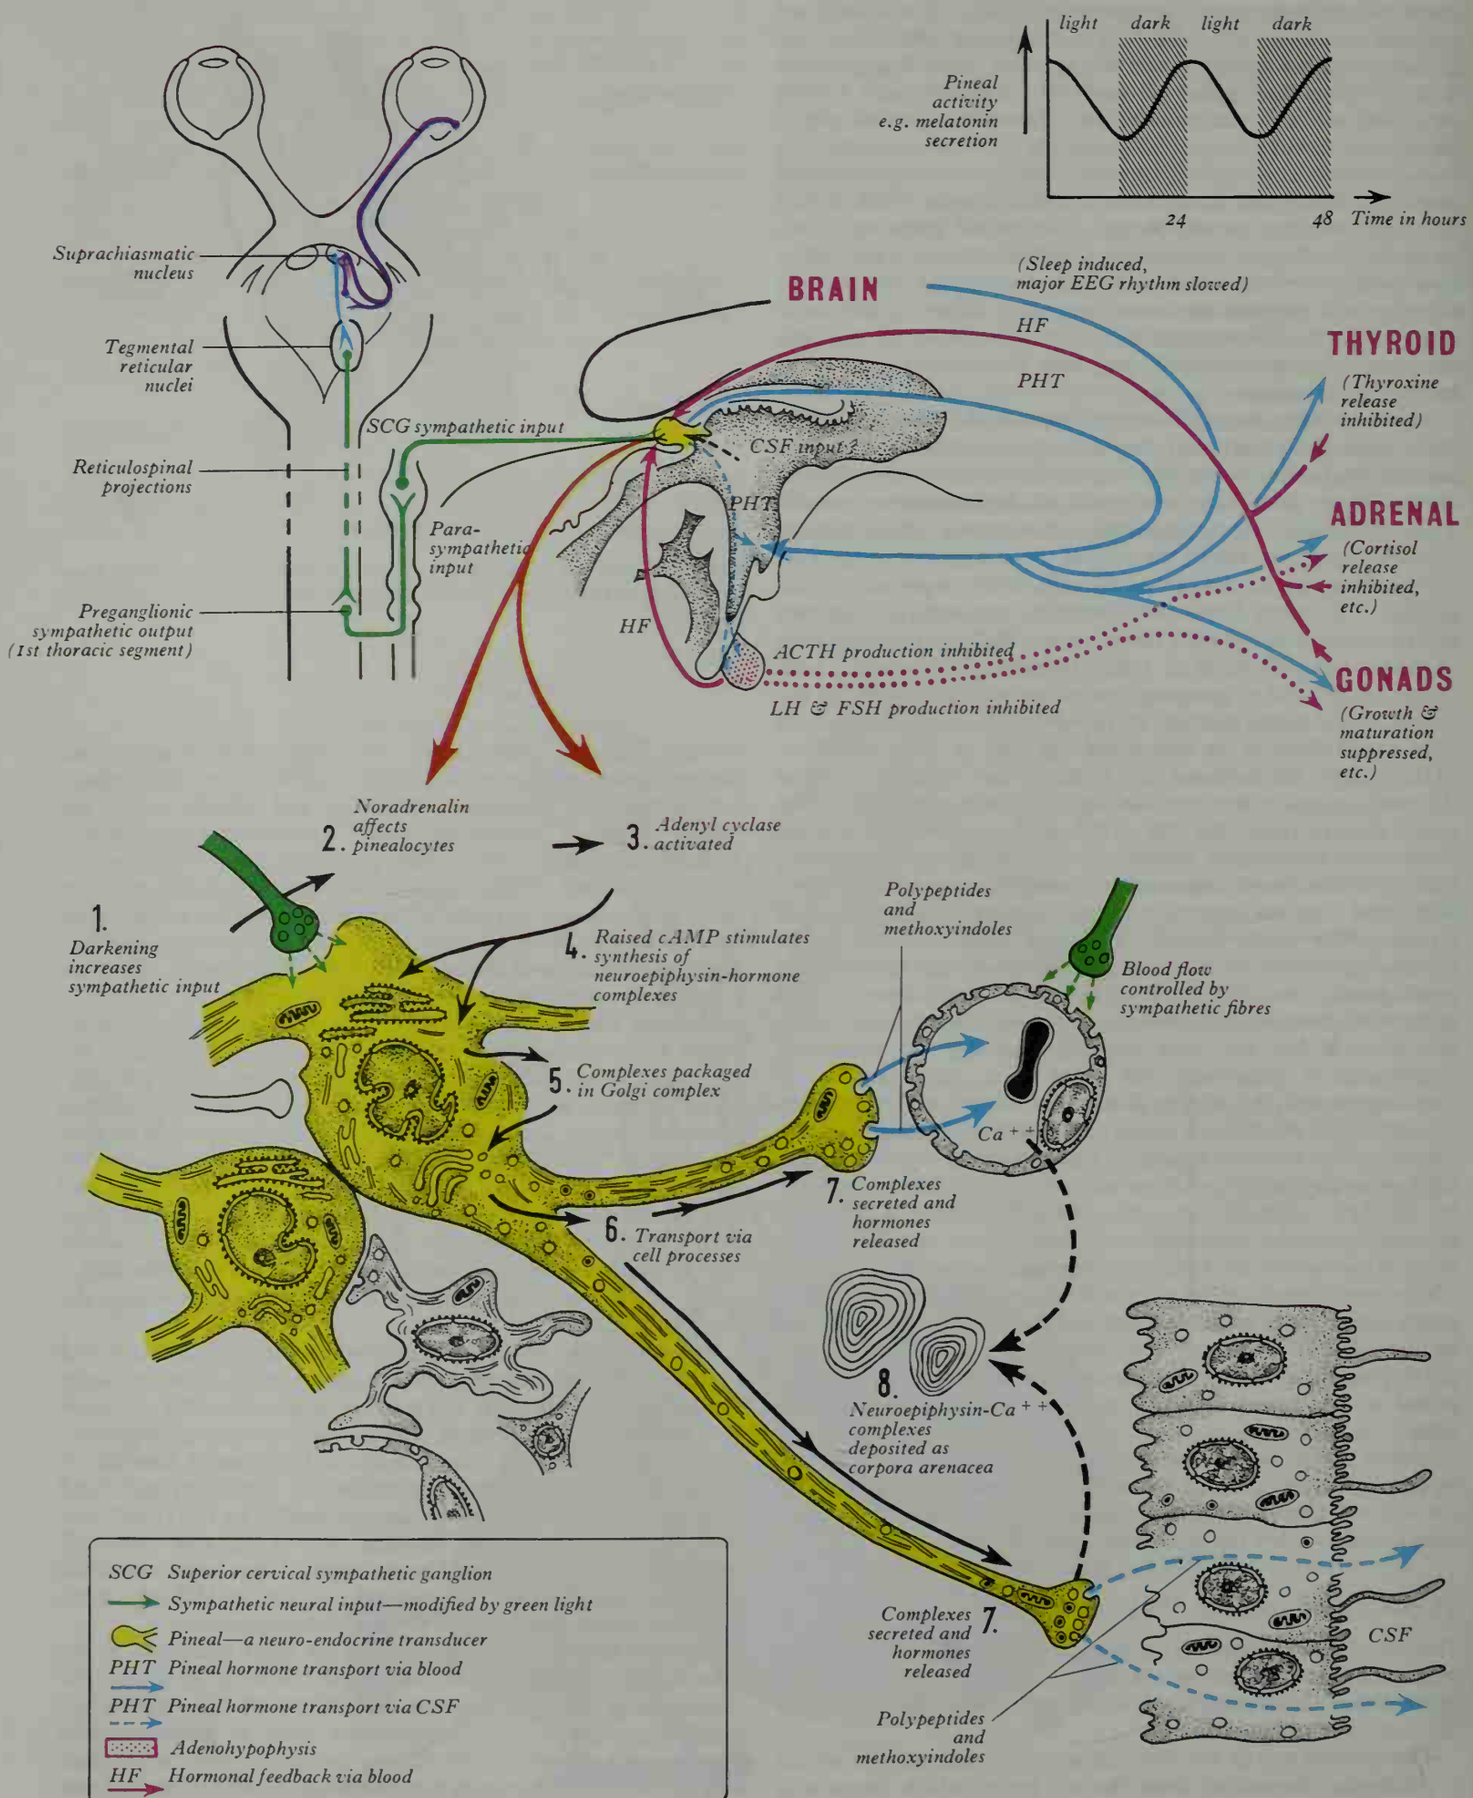
The Pineal Gland

The pineal gland or *epiphysis cerebi* (**8**.194) is a small, piriform, reddish-grey organ which occupies the depression between the superior colliculi. (For classical reviews *see* Gladstone and Wakeley 1940; Kappers 1960; Wolfe *et al.* 1962; Kappers and Schadé 1965; Wurtman *et al.* 1968; Wolstenholme and Knight 1971: and see below for more recent references.) It is inferior to the splenium of the corpus callosum, but is separated from it by the tela choroidea of the third ventricle and the contained cerebral veins. It is enveloped by the lower layer of the tela, which is then reflected over the tectum (**8**.194). The pineal gland measures about 8 mm in length, and its base, directed anteriorly, is attached by a *peduncle* or stalk which divides anteriorly into two laminae, superior and inferior, separated from each other by the *pineal recess* of the third venticle (**8**.194). The inferior lamina contains the posterior commissure (p. 963) and the superior lamina the habenular commissure (p. 962).

Aberrant commissural fibres may loop into the substance of the gland through its stalk, but they do not terminate in relation to parenchymal cells. Nerve fibres enter the dorsal or dorsolateral aspects of the gland from the region of the tentorium cerebelli where they form a single or paired *nervus conarii*. This runs in a subendothelial position in the wall of the straight sinus (p. 745) and its fibres are derived from the cells of the superior cervical ganglia. The nerve fibres are adrenergic sympathetic elements and run in association with blood vessels and parenchymal cells (Kappers 1960; Wolfe *et al.* 1962). Björklund *et al.* (1972) have shown in the rat that postganglionic sympathetic fibres from the *nervus conarii* supply neurons in the habenular nuclei, from which some of the fibres of the *habenulopineal tract* (p. 963) may arise. Møller (1978) has reported that in the human fetus, fibres from this tract extend to the *ganglion conarii* (Pastori ganglion) at the pineal apex (**8**.199A); the site of the perikarya of origin of these fibres needs verification. Møller (1978, 1979) has also described a hitherto undiscovered unpaired nerve containing non-myelinated fibres and bipolar neurons with axosomatic and axodendritic synapses, the *nervus pinealis*. in human fetuses; it lies in the subarachnoid space in or near the median plane just caudal to the pineal gland, connecting it with the posterior commissure; it is an ephemeral structure, presumed to degenerate late in intrauterine life, since it has not been found postnatally. Its functional significance is uncertain, but since it is presumed to be homologous with the sensory pineal nerve of fish and amphibians (Møller 1978) which have pineal complexes containing photoreceptive cells, it has been suggested that it might be able to transmit light-generated impulses. However, although in some mammals, for example neonatal rats, the pinealocytes have a transient photoreceptor-like ultrastructure (Zimmerman and Tso 1975) those of human fetuses do not, so this suggestion is not supported. The nervus pinealis of the human fetus could also be involved in pineal differentiation. In the absence of further information, it can be regarded as a phylogenetic vestige present briefly during development; its loss may be associated with the evolution of the pineal as a secretory (*vide infra*) rather than a photoreceptive organ.

Møller (1978) has also described a new ganglion, presumed to be parasympathetic, lying rostral to the pineal gland and close to the choroid plexus of the third ventricle. An anteriorly located *intrapineal ganglion* has also been found (**8**.199A).

8.199A A diagram showing the principal neural pathways which have been described in connexion with the human fetal pineal gland (epiphysis cerebri).



STRUCTURE OF THE PINEAL GLAND

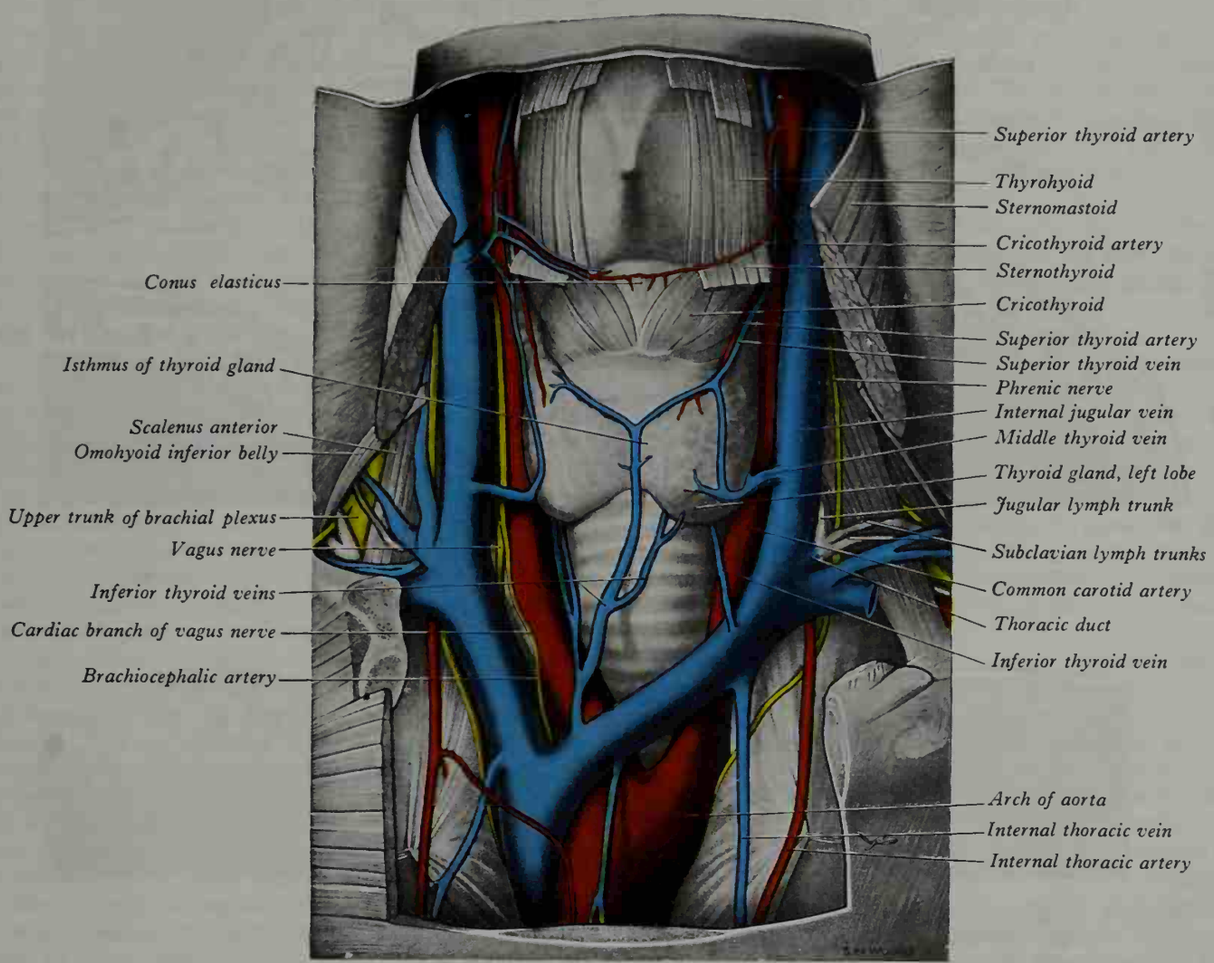
The pineal gland consists of cords and follicles of pinealocytes and neuroglial cells, between which ramify copious blood vessels and nerve fibres. Connective tissue septa extend into the gland from the surrounding pia mater.

The pinealocytes are the characteristic cells of the pineal parenchyma. Extending from the cell body, which contains a spherical, oval or lobulated nucleus, are one or more tortuous basophilic processes within which microtubules lie in parallel array (Knight *et al.* 1973). The processes end in slightly expanded terminal buds close to blood capillaries or, less frequently, near the ependymal cells of the pineal recess. The terminal buds contain granular endoplasmic reticulum, mitochondria and electron-dense cored vesicles. These vesicles store monoamines and polypeptide hormones (Sheridan and Sladek 1975), the release of which appears to require sympathetic innervation. Lukaszyk and Reiter (1975) have proposed that the polypeptide hormones (which in their opinion could also be produced by the neuroglial cells and neurons of the pineal) form complexes with specific carrier proteins, which they term *neuro-epiphysins* to distinguish them from the neurophysins of the pituitary. They are released by exocytosis, together with fragments of the vesicle membrane which contained them, the latter forming exocytotic debris. Once released, the complex is believed to dissociated, the hormones being exchanged from calcium ions. The calcium-carrier complex so formed is, in the case of the pineal, deposited in concentric layers around the exocytotic debris, forming *corpora arenacea* or '*brain sand*' (**8**.199B). No evidence supports the notion, once widely held, that the pineal atrophies with age and that the development of corpora arenacea is a sign of this atrophy; on the contrary, the presence of these multilaminar corpuscles may indicate continued secretory activity. Wildi and Frauchiger (1965) have found no evidence of pineal degeneration in the elderly.

The cell bodies of the pinealocytes contain both granular and agranular endoplasmic reticulum, together with extensive Golgi complexes, lipid droplets and numerous mitochondria, as befits cells with a secretory function. Occasionally an unusual organelle, consisting of groups of microtubules and perforated lamellae, is found close to the granular endoplasmic reticulum and lipid droplets. Termed '*canaliculate lamellar bodies*' by Lin (1967) and McNeil (1977), '*annulate lamellae*' by Friere and Cardinali (1975) and '*mikrotubuli*' by Gusek (1976), it has been suggested that these organelles may be involved in secretion (McNeil, 1977); their function is, however, as yet somewhat enigmatic.

Another feature of the pinealocyte of some mammals is the presence of synaptic ribbons, which may be involved in impulse transmission between adjacent cells. Close to the ribbons are vesicles containing neurotransmitters such as gamma amino butyric acid (Krstic 1976). These structures may arise from microtubular sheaths which in turn arise from centrioles (Karasek 1976). Similar arrangements of organelles have been found in the photoreceptor cells of the mammalian retina and in the simpler photoreceptor cells of a range of submammalian vertebrates, supporting the theory that the mammalian pinealocyte is phylogenetically derived from a photoreceptive element (Kap-

8.199B A diagrammatic review of current hypotheses regarding the control and effects of pineal function. (See p. 1447 for details.)



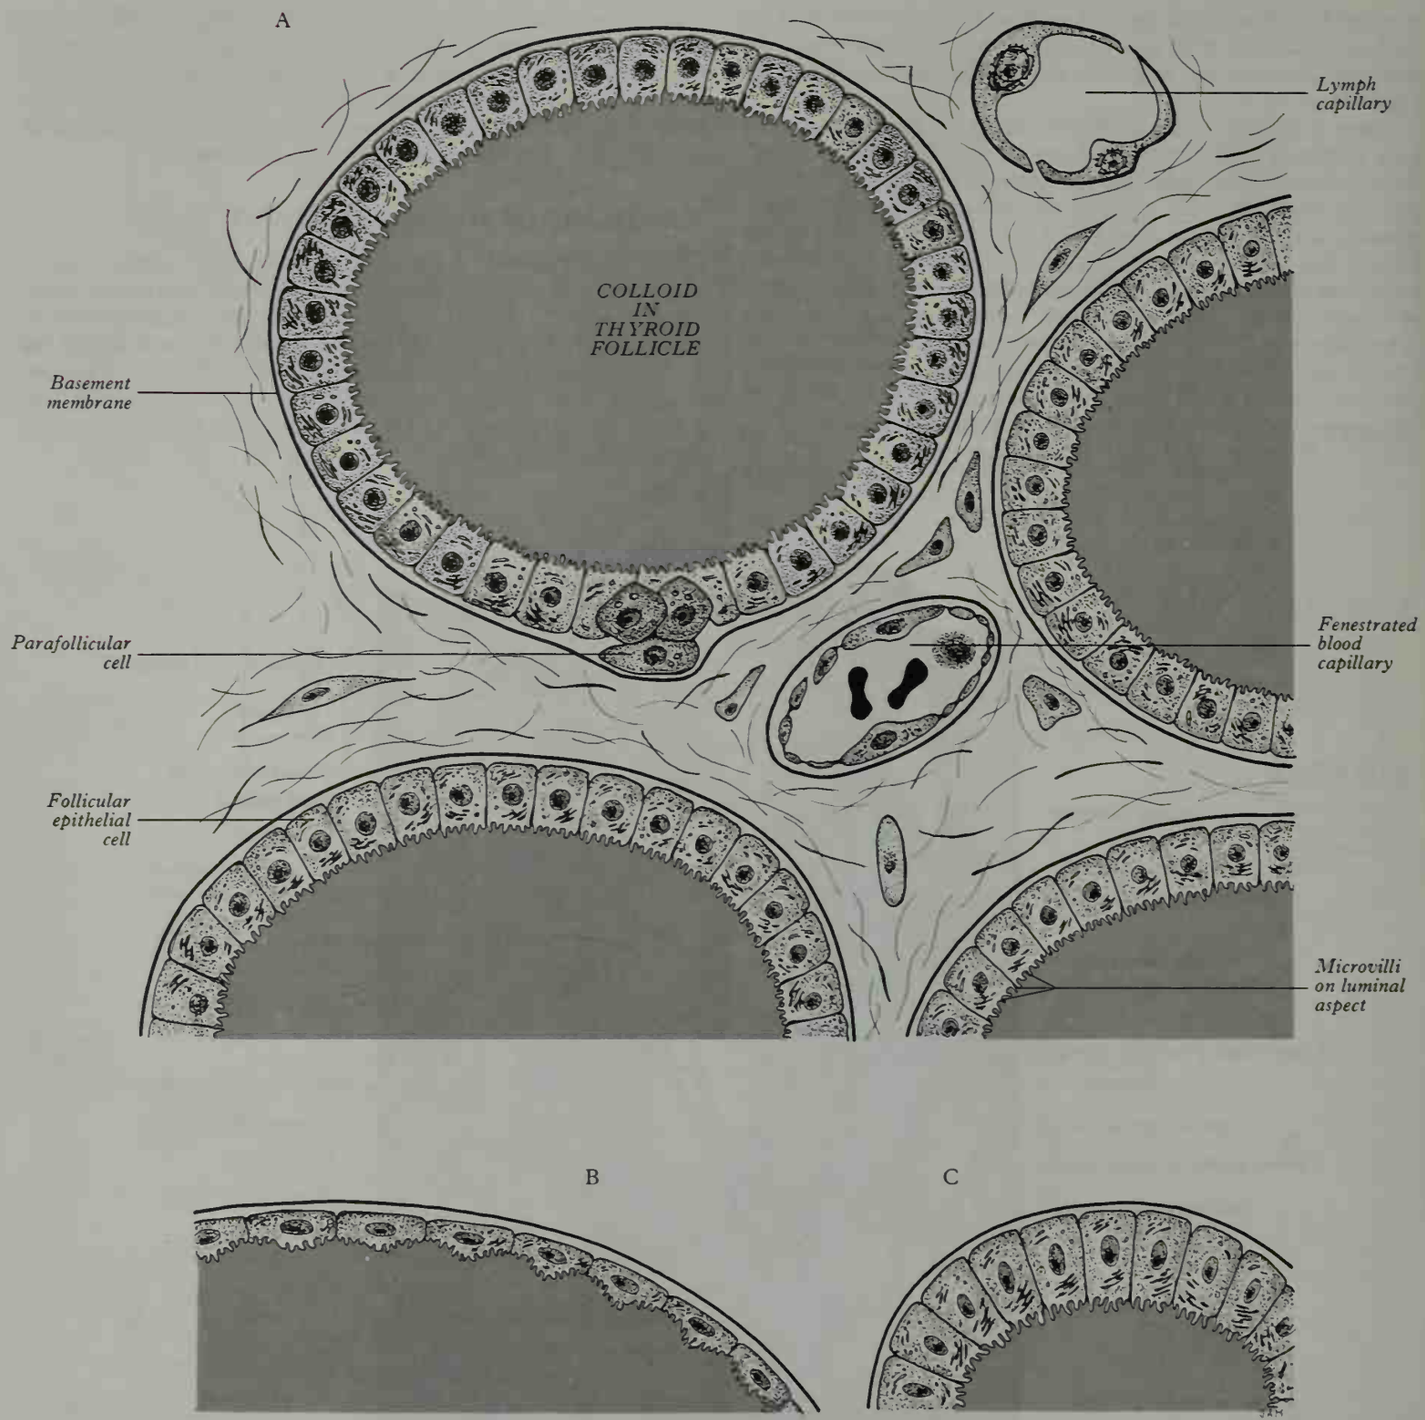
pers 1976; Relkin 1976). Further support for this comes from the finding by Zimmerman and Tso (1975) of a transient similarity between pinealocytes and retinal photoreceptor cells in the neonatal rat.

There is ultrastructural evidence that human fetal pinealocytes have a secretory function early in intrauterine life (Møller, 1974). As in adults, they contain all the organelles necessary for such activity, together with copious microfilaments, some microtubules, and occasional cilia with a 9+0 microtubular pattern. Cilia of this type are also associated with secretory cells of other endocrine glands, such as the pituitary (Barnes 1961; Andersen *et al.* 1970). Fetal pinealocytes are linked by gap junctions, desmosomes and 'intermediate-like junctions' (Møller 1976); the first of these allows for electrotonic coupling between adjacent pinealocytes and could make group activity possible, while the others may be of an adhesive nature. Synaptic ribbons do not appear to be present in human fetal pinealocytes.

(*vide supra*), or directly through the leptomeningeal surface of the pineal. They terminate either in the perivascular spaces, between the pinealocytes, or occasionally in synaptic relation with these cells. The nerve fibres passing along the pineal stalk from other brain centres are of rather imprecise origin, but the habenular complex of nuclei has become a strong proponent.

FUNCTIONS OF THE PINEAL GLAND

Once considered to be a phylogenetic relic, the vestigial remains of a dorsal third eye, and an organ of little functional significance, the mammalian pineal gland has now been demonstrated to be an endocrine gland of major regulatory importance, modulating the activity of the adenohypophysis, neurohypophysis, endocrine pancreas, parathyroids, adrenal cortex, adrenal medulla and gonads (De Vries and Kappers 1971; Kappers 1976; Relkin 1972; Reiter 1977; Klein 1978).



8.200 The thyroid gland and its environs. The manubrium sterni and the sternal ends of the clavicles and first costal cartilages have been removed and the pleural sac and lung have been retracted on each side.

The neuroglial cells are situated amongst the pinealocytes which they partially ensheath and separate. They are similar to astrocytes, and many of those situated in the pineal stalk have highly elongated cytoplasmic processes which pass longitudinally, composing most of the substance of the stalk. Ultrastructurally these glial elements are seen to possess numerous filaments which extend to all parts of their cytoplasmic processes.

The *capillaries* of the pineal are lined by thin and sometimes fenestrated endothelial cells, external to which is a tenuous basal lamina, sometimes incomplete. Most non-myelinated autonomic *nerve fibres* are noradrenergic, containing dense-cored vesicles in their terminal and pre-terminal expansions. These nerve fibres, which arise from the superior cervical ganglion, penetrate the pineal either by way of perivascular spaces, or via the nervi conarii

In general, the effects of pineal secretions are inhibitory. The indole-amine and polypeptide hormones secreted by its pinealocytes are believed to reduce the level of synthesis and release of various hormones of the pars anterior, for example, both by direct action on the secretory cells of the gland, and indirectly by inhibiting the production of releasing factors within the hypothalamus. The pineal secretions may reach their target cells either via the cerebrospinal fluid (Sheridan *et al.* 1969; Knight *et al.* 1973) or via the circulatory system.

A number of pineal indole-amines, including melatonin, and the enzymes necessary for their biosynthesis, such as serotonin N-acetyltransferase, show a circadian rhythm in their concentration and activity within the pineal glands of a variety of mammals. In the rat there appears to be an *endogenous circadian oscillator* in the

8.201 A–C Diagrams of thyroid follicular structure. A Normal structure under average physiological conditions. B 'Resting' state. C Highly active state. (See text for details.)

suprachiasmatic nucleus of the hypothalamus, whose intrinsic rhythmicity is responsible for the cyclical behaviour of the pineal (Klein 1978). Photic stimuli, in particular changes in the level of yellow-green light acting on a rhodopsin-like retinal photopigment, seem to be involved in regulating this rhythm (Cardinali *et al.* 1971; Minneman *et al.* 1974), with the result that the pineal gland is most active during darkness. If the visual system and the sympathetic nerve supply of the pineal gland remain intact, exposure to light after several hours of darkness depresses pineal activity (Klein and Weller 1972). Neurons of the suprachiasmatic nucleus are supplied directly by axons of retinal nerve cells, allowing response to changes in illumination (Nishino *et al.* 1976). In the rat the neuronal pathway from the suprachiasmatic nucleus to the pineal gland includes the tegmental nuclei and the upper thoracic intermediolateral cell column (Saper *et al.* 1976). Preganglionic sympathetic fibres from the latter pass to the superior cervical ganglia, from which postganglionic fibres can be traced to the pinealocytes. The release of catecholamines from these fibres causes a receptor-mediated increase in the production of cyclic AMP in the pinealocytes, which in turn triggers a 70- to 100-fold increase in the activity of serotonin N-acetyltransferase activity, and is responsible for the daily changes in melatonin production and hence in plasma melatonin levels. So far interest has centred on the sympathetic innervation of the pineal; the gland also has a parasympathetic supply but its role in the control of pineal activity is as yet unknown. (The foregoing general hypotheses are summarized in **8**.199B.)

There is now evidence of the existence of a circadian rhythm in human pineal activity, as demonstrated by changes in plasma melatonin levels (Vaughan *et al.* 1976). As in other mammals, the level rises during darkness and falls during the day. Whether or not control mechanisms similar to those so elegantly demonstrated in other animals also operate in man remains to be resolved.

The Thyroid Gland

The thyroid gland (**8**.200) is a brownish-red, highly vascular organ, situated anteriorly in the lower part of the neck, at the level of the fifth, sixth and seventh cervical and the first thoracic vertebrae. It is ensheathed by the pretracheal layer of the deep cervical fascia, and consists of right and left lobes connected across the median plane by a narrow region, termed the *isthmus*. Its weight is somewhat variable, but is usually about 25 g. It is slightly heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The lobes are approximately conical in shape, the apex of each ascending and diverging laterally to the level of the oblique line of the thyroid cartilage; the base is on a level with the fourth or fifth tracheal 'ring'. Each lobe is about 5 cm long; its greatest transverse and anteroposterior dimensions being about 3 cm and 2 cm. The posteromedial aspect of each lobe is attached to the side of the cricoid cartilage by a ligamentous band, called the *lateral ligament* of the thyroid gland (p. 1081). The *lateral* or *superficial surface* is convex. External to the sheath of pretracheal fascia, this aspect of the gland is closely covered with the sternothyroid and it is the insertion of this muscle into the oblique line on the lamina of the thyroid cartilage which prevents the upper part of the lobe from extending on to the thyrohyoid muscle. More anteriorly still are the sternohyoid and the superior belly of the omohyoid, overlapped below by the anterior border of the sternocleidomastoid. The *medial surface* is adapted to the larynx and trachea. At its superior pole, it is in contact with the inferior pharyngeal constrictor and the posterior part of the cricothyroid, which intervene between the gland and the posterior part of the lamina of the thyroid and the side of the cricoid cartilages. The external laryngeal nerve is medial to this part of the gland on its way to the cricothyroid. Below, it is related to the side of the trachea in front and to the recurrent laryngeal nerve (*see* p. 1081) and (especially on the left side) to the oesophagus posteriorly. The *posterolateral surface* is related to the carotid sheath and overlaps the common carotid artery. The *anterior border*, closely related to the anterior branch of the superior thyroid artery, is thin and descends obliquely and medially. The *posterior border*, blunt and rounded, is between the posterior and the medial surfaces and is closely related below to the inferior thyroid artery and an anastomosing branch which connects it to the posterior branch of the superior thyroid artery. In addition, the parathyroid glands are usually related to the posterior border (p. 1453) The lower end of the posterior border of the left lobe is closely related to the thoracic duct.

The isthmus connects the lower parts of the two lobes; it measures about 1·25 cm transversely, and the same vertically, and usually extends anterior to the second and third rings of the trachea, though it is often placed at a higher, or occasionally lower, level. Its situation and size present, however, many variations. Anteriorly, it is separated by the pretracheal fascia from the sternothyroids. More superficially it is covered by the sternohyoids, the anterior jugular veins, the fascia and the skin. An anastomotic branch uniting the two superior thyroid arteries runs along its upper border; at its lower border the inferior thyroid veins leave the gland. Occasionally the isthmus is absent.

A third, conical *pyramidal lobe* is often present; it ascends towards the hyoid bone from the upper part of the isthmus, or from the adjacent part of either lobe (more commonly the left). It is occasionally quite detached, or may occur as two or more separate parts.

A fibrous or fibro-muscular band sometimes descends from the body of the hyoid bone to the isthmus of the gland, or its pyramidal lobe; when muscular, it is termed the *levator of the thyroid gland*.

Small detached masses of thyroid tissue sometimes occur in the vicinity of the lobes or superior to the isthmus; they are called *accessory thyroid glands*. Vestiges of the thyroglossal duct (p. 198) may persist between the isthmus and the foramen caecum of the tongue, and may give rise to accessory nodules or cysts of thyroid tissue, situated in or near the median plane, and even in the substance of the tongue.

Structure. The thyroid gland is invested by a thin capsule of connective tissue and it is divided into masses of irregular form and size by extensions of this connective tissue. The thyroid parenchyma is mainly derived from the endoderm of the thyroglossal duct (p. 198), a generally ephemeral structure which in the embryo connects it to the tongue. Branching, solid, epithelial cords and sheets grow out from the distal end of the duct, and lumina filled with a yellow, viscid colloid appear within them. The endodermally derived epithelia are usually considered to develop into separate follicles, approximately spherical structures of from about 0·02 to 0·9 mm in diameter, each consisting of a central core of colloid surrounded by a single layer of epithelial cells and enclosed in a basal lamina; however, three-dimensional reconstructions of mature thyroid glands have shown that the follicles are not usually separate units, but typically occur as aggregates, with a shared sheet of epithelial cells bordering on several masses of colloid, and thus linking the follicles together (Isler *et al.* 1968). The colloid, which stains pink with eosin, consists of the iodinated glycoprotein thyroglobulin, a precursor of the thyroid hormones tri-iodothyronine (T_3) and tetra-iodothyronine or thyroxine (T_4), and is a product of the follicular epithelial cells which surround it.

The aggregates of follicles nestle in the delicate connective tissue stroma of the gland, surrounded by close-meshed plexuses of fenestrated blood capillaries. The stroma also contains an extensive network of lymphatic vessels. Sympathetic nerve fibres supply the arterioles and capillaries, and some end in apposition to the follicular epithelial cells (Melander *et al.* 1975; Melander 1977).

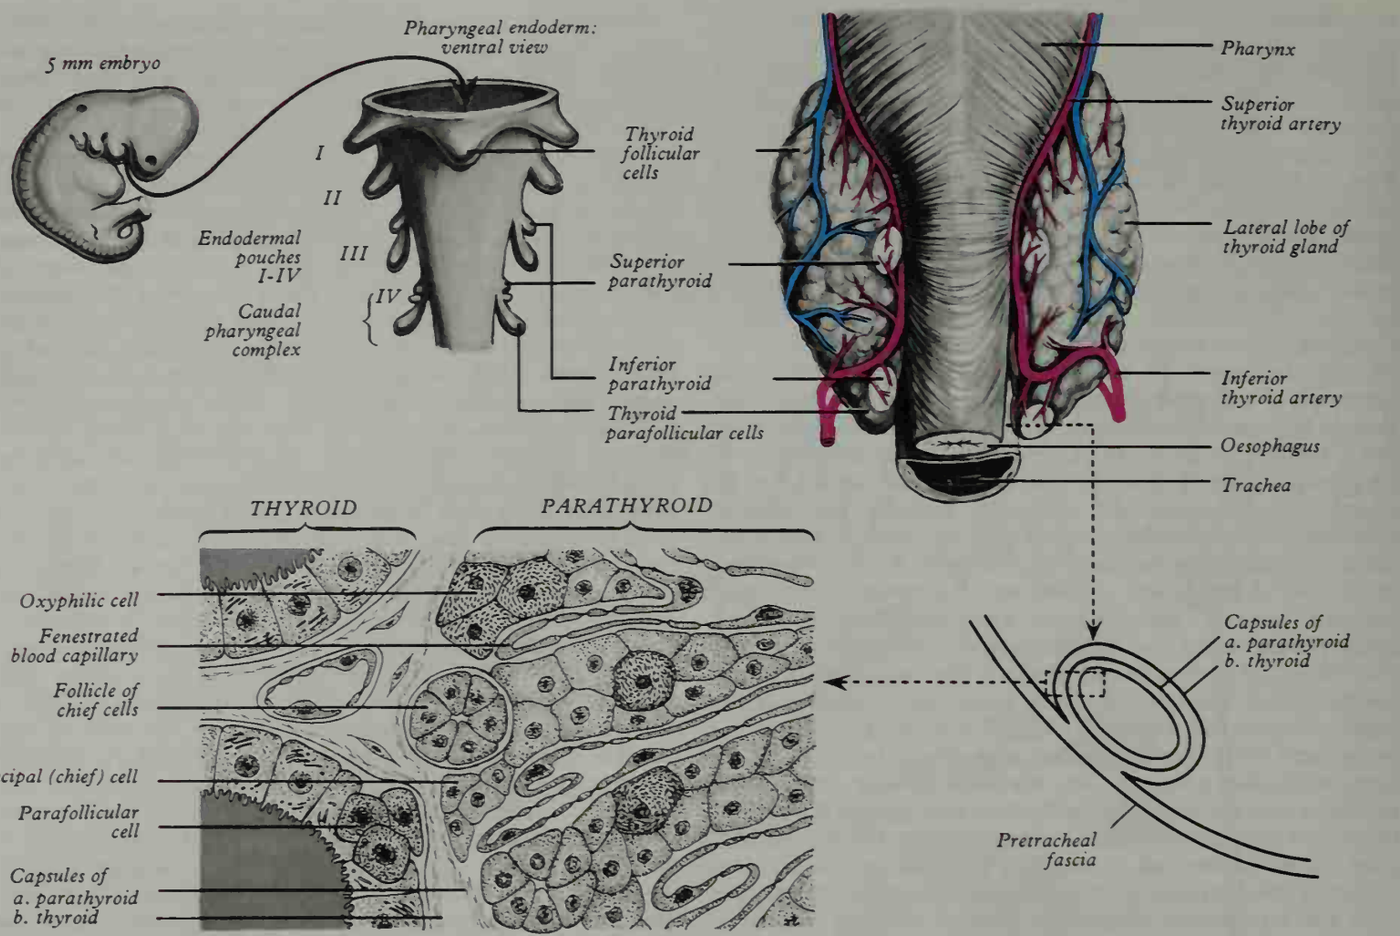
In addition to the follicular cells proper, the thyroid parenchyma contains a second cell type, the parafollicular, light, clear or C cells, which produce the peptide hormone thyrocalcitonin. The C cells are a form of APUD cell (p. 1454), and are derived from the ultimobranchial bodies (p. 199). They are a minor component of the parenchyma, although the application of improved detection techniques for these cells (Solcia *et al.* 1968, 1969) suggests that in some species their numbers may be higher than previously estimated; in the dog, for example, Kameda (1971, 1976) has found from 30 to 90 parafollicular cells per 100 follicular cells. Occasionally branched tubules containing desquamated cells are found in the thyroid gland; like the C cells, these are of ultimobranchial origin (Halmi 1978). Other cell types, including ciliated cells, have been described in the thyroid glands of rodents (Wollman and Nève 1971); their functional significance is uncertain.

The *follicular cells proper* vary in shape between squamous and columnar, depending on their level of activity, which is mainly controlled by circulating pituitary thyrotropin (**8**.201). In the absence of thyrotropin (TSH), the follicular cells are squamous and are referred to as 'resting', while the luminal colloid is copious and dense, reflecting increased storage of iodinated thyroglobulin. The secretion of TSH is followed by the uptake of colloidal droplets from the lumen by endocytosis at the luminal aspect of the follicular cells, and cavities may be seen in the luminal colloid where it adjoins the epithelium (**8**.202). The prolonged action of high levels of circulating TSH induces follicular cell hypertrophy and even hyperplasia, accompanied by the progressive resorption of luminal colloid and an increase in stromal vascularity.

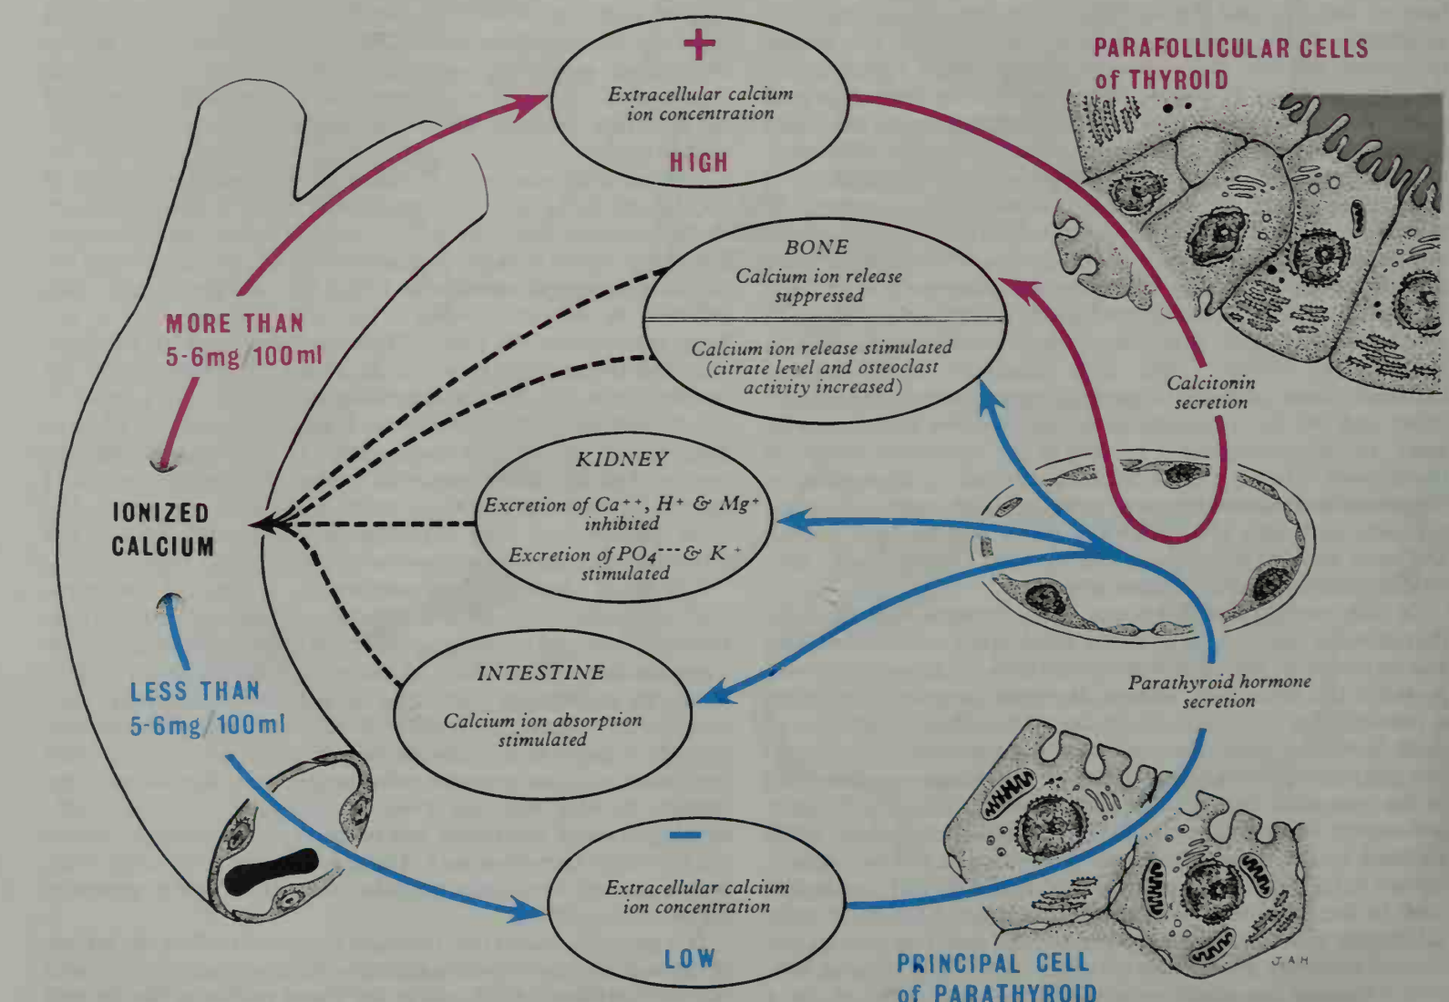
The follicular cells have a striking ultrastructural and functional polarity. They are concurrently engaged, when activated by TSH or possibly by adrenergic nerve terminals (*vide infra*), in the apically (that is, luminally) directed processes of thyroglobulin synthesis and exocytosis, and in the basally directed processes of thyroglobulin endocytosis, degradation, and liberation of the thyroid hormones T_3 and T_4 into the blood capillaries. This dual polarity of function is reflected in the arrangement of the organelles concerned with these processes. Collectively forming a continuous wall around each mass of colloidal thyroglobulin, the follicular cells are linked at their apices by junctional complexes, and lie with their bases resting against a basal lamina (**8**.201 and **8**.202). Each follicular cell has a basally disposed nucleus, prominent granular endoplasmic reticulum, and a supranuclear Golgi complex, the last being particularly prominent in TSH activated cells. Lying above the Golgi complex, in the apical half of the cell, are numerous Golgi-derived secretory vesicles which transport the glycoprotein

8.202 The functional architecture of the thyroid follicular cells, showing on one aspect the colloid-containing cavity, and on the other blood and lymphatic capillaries. Arrows indicate metabolic flow pathways.

manufactured by the consecutive activity of the rough endoplasmic reticulum and the Golgi complex to the apical plasmalemma, where it is released by exocytosis into the lumen of the follicle. The iodine required to complete the formation of thyroglobulin enters the basal aspect of the follicular cells in the form of iodide by active transport across the basal plasmalemma from the blood capillaries, and quickly assumes a predominantly luminal location (Wolff 1964). Here it is rapidly oxidized to iodine, mainly by the activity of thyroid peroxidase in the apical plasmalemma (Taurog 1970). The iodine then becomes attached to the tyrosyl groups of the secreted glycoprotein manufactured by the follicular cells, forming mono- and di-iodotyrosyls. Coupling of these results in the formation of iodothyronyl groups (thyroid hormones in peptide linkage) and completes the formation of iodinated thyroglobulin, the large precursor of the thyroid hormones (Bjorkman and Ekholm 1973; Robbins *et al.* 1974; Haeberli *et al.* 1975). Investigation of the distribution of endogenous peroxidase in the follicular cells has shown it to be present in the perinuclear cisternae, granular endoplasmic reticulum, Golgi complex, apical vesicles, and at the apical plasmalemma, particularly over the microvilli which project into the lumen of the follicle (Strum and Karnovsky 1970). It is believed, however, that it is only when incorporated into the apical plasmalemma that it is involved in iodide oxidation, and that the rest of its distribution indicates the route along which it passes to reach this site. The apical microvilli are numerous but short in resting follicular cells (Wetzel *et al.* 1965), but become longer and often branched after stimulation by TSH. Such stimulation also results in the extension of long cytoplasmic processes into the luminal colloid; these fuse around portions of the colloid with the result that it is taken up into the cell. Shortly after colloid endocytosis, lysosomes, which in the resting state tend to be basal in position, migrate to the apex of the cell and fuse with the intracellular droplets of colloid, forming secondary lysosomes or phagolysosomes. These then migrate back to the base of the cell, and during this period the colloid gradually disappears as the acid proteases and peptidases of the phagolysosomes degrade the iodinated thyroglobulin releasing the thyroid hormones T_3 and T_4. These pass to the base of the cell where they are released, leaving the gland mainly via the blood capillaries. The more numerous precursor molecules 3-monoiodotyrosine and 3,5-di-iodotyrosine are de-iodinated by a dehalogenase, and the iodine released migrates apically to be reused in the iodination of newly synthesized thyroglobulin molecules. Both microtubules and microfilaments appear to be actively involved in thyroid hormone secretion (Wolff and Williams 1973), for treatment with colchicine and cytochalasin B, which interfere with microtubule and microfilament activity respectively, inhibit TSH and dibutyryl cAMP-induced secretion. Some iodinated thyroglobulin escapes from the follicles intact and can be demonstrated in the blood by radioimmunoassay, probably reaching it by way of the lymphatic vessels of the thyroid. The activity of the follicular cells in thyroglobulin formation and thyroid hormone secretion is illustrated diagrammatically in **8**.202. The reviews of Greer and Haibach (1974), DeGroot and Niepomniszcze (1977), and Taurog (1978) provided detailed accounts of these processes.



Of the two thyroid hormones, it is thought that tri-iodothyronine in the body cells is the chief agent which stimulates and increases the rate of cellular metabolism, its action being very powerful and immediate, whereas *thyroxine* (tetra-iodothyronine) is powerful but delayed in its similar action. Over-production of these hormones causes the condition of *thyrotoxicosis* (exophthalmic goitre); hyposecretion in the adult produces *myxoedema*, and in the post-natal period, *cretinism* (p. 822). Their development and activity are mainly controlled by thyrotropic hormone (TSH) secreted by the adenohypophysis. However, in *Graves' disease*, human thyroid-stimulating immunoglobulin (HTSI) antibodies bind to the TSH-receptor sites on the thyroid follicular cells, interfering with this control mechanism and resulting in excessive thyroid hormone production (Werner 1978). The thyroid hormones increase the sensitivity of the body tissues to the effects of adrenalin and noradrenalin secreted by the medulla of the suprarenal glands.



Although the activity of the follicular cells is mainly controlled by the level of circulating TSH, there is considerable evidence in a number of mammalian species, including man, of a direct sympathetic influence on the follicular cells, in addition to that induced by sympathetically mediated changes in the microcirculation of the gland (Melander 1978). Fluorescence histochemistry and electron autoradiography have been used to demonstrate the presence of adrenergic nerve terminals associated with both blood vessels and follicular cells. In mice where TSH secretion has been eliminated to avoid indirect effects on thyroid secretion, unilateral stimulation of the sympathetic fibres supplying the thyroid induces secretion of thyroid hormones only in those regions of the gland innervated by the stimulated nerve (Melander *et al.* 1972). Furthermore, studies using normal human thyroid tissue *in vitro* suggest that noradrenalin can directly induce changes within the follicular cells which might be expected to lead to thyroid hormone secretion; the changes noted included intracellular colloid droplet formation and lysosome migration (Melander 1978). Similar *in vitro* investigations using isolated calf thyroid cells have shown that catecholamines can enhance the incorporation of iodine and synthesis of thyroid hormones (Melander *et al.* 1973). The stimulation of follicular cell activity induced by catecholamines can be abolished both *in vivo* and *in vitro* by drugs that block adrenergic receptors (Melander 1970, Maayan and Ingbar 1978). Treatment with these agents does not, however, affect the abililty of the cells to respond to TSH. It would thus appear that catecholamines and TSH interact with different receptors on the follicular cell surface, and that they can act independently. The effects which they set in motion are, however, similar; both induce activation of adenyl cyclase, resulting in increased formation of cyclic-AMP, which leads to increased release of thyroid hormones (Melander 1978). Although there can be little doubt from the results of both anatomical and physiological investigations that follicular cells as well as blood vessels have a direct sympathetic innervation, the degree and significance of sympathetic control of thyroid hormone secretion is uncertain. Although TSH may be of greater importance as a long term regulator of thyroid activity, the existence of a link between the sympathetic nervous system and the follicular cells may provide for rapid secretory responses to certain stimuli.

The *parafollicular cells* (C, clear or light cells) are a type of APUD cell (p. 1454). They are situated singly or in small groups in the spaces between the follicles of the thyroid, with the outer borders of which they are in close juxtaposition, lying within the follicular basement membrane. Often they are partly insinuated between the adjacent borders of follicular cells, but they do not reach the lumen of the follicle. They are larger than the follicular cells and are polyhedral or oval in outline. The grouping of the parafollicular cells is sometimes more marked as, for example, in the thyroid gland of dogs that have been perfused with fixative in preparation for electron microscopy. In this case follicle-like groups of such cells are seen, with expanded central extracellular spaces; it is possible that these spaces act as a hormone store, but more evidence of their significance is required. Unlike the follicular cells, they do not appear to have a direct nerve supply.

The most distinctive ultrastructural feature of the parafollicular cells is the presence in their cytoplasm of numerous membrane-bound secretory granules. It is generally assumed that these contain a stored form of the peptide hormone thyrocalcitonin, an assumption supported by immunocytochemical light microscope studies (Pearse 1966; Wolfe *et al.* 1974). As befits cells actively engaged in the manufacture of exportable protein, their cytoplasm contains granular endoplasmic reticulum whose form appears to vary with the level of activity of the cells, well-developed Golgi complexes and numerous mitochondria. There are also many free ribosomes. The nucleus is approximately oval, with a smooth or slightly irregular membrane, and is generally eccentric in position.

It is generally stated that the main factor controlling the release of thyrocalcitonin is the concentration of serum calcium: a rise in the concentration of calcium in the blood perfusing the thyroid stimulates thyrocalcitonin secretion, while hypocalcaemia suppresses it, and there is thus a reciprocal relationship between

8.203 Diagrammatic representation of the roles of the parathyroid and thyroid glands in the control of calcium metabolism.

the secretion of thyrocalcitonin and the secretion of parathyroid hormone (**8**.203). However, while thyrocalcitonin would appear to be an important regulator of calcium metabolism in many species, acting predominantly by suppressing bone resorption, its status in man in uncertain. This uncertainty stems in part from the difficulties which have been encountered in detecting thyrocalcitonin in normal human plasma even with highly sensitive radioimmunoassays, and in part from the failure as yet to detect a disease associated with thyrocalcitonin deficiency (O'Riordan 1978).

Vessels and nerves. The *arteries* supplying the thyroid gland are the superior (p. 698) and inferior thyroid arteries (p. 678); sometimes there is an additional *lowest* thyroid artery, the *arteria thyroidea ima*, a branch from the brachiocephalic trunk or the aortic arch which ascends upon the front of the trachea. The arteries are remarkable for their large size and frequent anastomoses, not only on the surface of the gland, but also in its substance. The *veins* form a plexus on the surface of the gland and on the front of the trachea; from this plexus the superior, middle and inferior thyroid veins arise; the superior and middle end in the internal jugular vein, the inferior in the left brachiocephalic vein. The capillary blood vessels form a dense plexus in the connective tissue around the follicles, between the epithelium of the follicles and endothelium of the lymph capillaries which surround a greater or smaller part of the circumference of the follicle. The *lymph vessels* run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland; they may contain colloid material. They end in the thoracic duct and the right lymphatic duct. The *nerves* are derived from the superior, middle and inferior cervical ganglia of the sympathetic.

Applied Anatomy. Apart from variable but often considerable enlargement during menstruation and pregnancy, which is regarded as being within physiological limits, any enlargement of the thyroid gland is called a goitre. Pressure may be exerted by the enlarged gland on any of the structures related to it. Symptoms are most commonly due to pressure on the trachea or recurrent laryngeal nerves. The external laryngeal nerve or the cricothyroid (which is supplied by the nerve and whose action is to render tense the vocal folds) may be damaged by the pressure of a much enlarged thyroid gland or in the operation of thyroidectomy. In such cases the voice becomes monotonous in character, incapable of varying its pitch, and slightly tremulous (Harries 1955).

Partial extirpation of the thyroid may be required in hyperthryoidism and other conditions of thyroid enlargement. Enough of the gland is removed to relieve symptoms, but, except in malignant disease, the whole gland is not removed, for this is followed by the development of myxoedema. In ligating the inferior thyroid artery, the position of the recurrent laryngeal nerve (pp. 698 and 1080) must be remembered, lest it should be also ligated and divided. Temporary aphonia not uncommonly follows from mere bruising of the nerve and, if nothing more serious has occurred, soon passes off. In partial removal of the thyroid gland it is customary to leave behind the posterior part of each lobe, because during its removal there is great risk of coincident removal of the parathyroid glands with resultant serious disturbance of calcium metabolism.

The Parathyroid Glands

The parathyroid glands (**8**.203) are small, yellowish-brown, ovoid or lentiform structures, which usually lie between the posterior borders of the lobes of the thyroid gland and its capsule. They vary in size, but commonly measure about 6 mm longitudinally, 3–4 mm transversely, and 1–2 mm anteroposteriorly; each weighs about 50 mg. Usually there are four, two on each side, and they are called, from their positions, the superior and inferior parathyroids. The anastomotic artery connecting the superior to the inferior thyroid artery runs along the posterior border of the lobe of the thyroid gland (p. 678) and, as it usually passes very close to the parathyroids, it forms a good guide to them.

The *superior parathyroid gland* is more constant in position than the inferior parathyroid, and is usually situated at the level of the middle of the posterior border of the lobe of the thyroid gland, though it may lie at a higher level. The *inferior parathyroid gland* may lie in various positions (Walton 1931; Gilmour 1938; Murley and Peters 1961), e.g. (1) within the fascial sheath of the thyroid gland, below the inferior thyroid artery and near the inferior pole of the lobe of the thyroid; (2) behind and outside the fascial sheath of the thyroid gland, immediately above the inferior thyroid artery; or (3) within the substance of the lobe of the thyroid gland near the inferior end of its posterior border. These variable positions are important surgically, since a tumour of the inferior parathyroid which occupies position (1) tends to descend along the inferior thyroid veins, in front of the trachea into the superior mediastinum of the thorax, whereas if the gland occupies position (2) the tumour tends to extend postero-inferiorly, behind the oesophagus into the posterior mediastinum. The superior parathyroids are usually dorsal, and the inferior pair ventral, to the recurrent laryngeal nerves (Pyrtek and Painter 1964).

The parathyroid glands are developed from the endoderm of the pharyngeal saccules or pouches (p. 199), the inferior parathyroids from the third pouch and therefore referred to as parathyroids III, and the superior parathyroids from the fourth pouch and therefore called parathyroids IV. The inferior parathyroid is closely connected in the early stages of its development with the diverticulum from the third pouch, which forms the thymus, and it is drawn down with the thymus in the caudal migration of the latter. Normally the inferior parathyroid migrates only as far as the inferior pole of the lobe of the thyroid gland, but it may descend with the thymus into the thorax, or it may not descend at all and remain above its normal level, near the bifurcation of the common carotid artery.

The parathyroid glands vary in number; there may be many minute islands of parathyroid tissue scattered in the connective tissue in the region of the usual position of the glands, or there may only be three (Hintzsche 1937; Vail and Coller 1967).

Vessels and nerves. The parathyroid glands receive a very rich blood supply from the *inferior thyroid arteries* or from the anastomoses between the superior and inferior thyroid arteries. Their *lymph* vessels are numerous, and are associated with those of the thyroid and thymus glands. Their *nerve supply* is derived from the sympathetic, either directly from the superior or middle cervical ganglia, or indirectly through a plexus in the fascia on the posterior surface of the lobes of the thyroid gland. The nerves are not secretomotor in function, but probably vasomotor, and parathyroid activity appears to be controlled by alterations in the calcium content of the blood, being inhibited by a rise and stimulated by a fall.

Structure (**8**.203). Each parathyroid has a thin connective tissue capsule, from which septa pass into the gland but do not subdivide it into distinct lobules. In the child, the gland consists of wide, irregular anastomosing columns or cords of cells, the *chief cells* (or *principal cells*). These cells are responsible throughout life for the synthesis and secretion of parathyroid hormone (or parathormone). Three types of chief cell, namely *light*, *dark*, and *clear*, can be distinguished according to the depth of staining of their cytoplasm, which by light microscopy appears homogenous. Between the columns of cells lies a rich network of sinusoidal capillaries, via which parathyroid hormone leaves the gland.

The ultrastructure of parathyroid glands was reviewed in detail by Capen in 1975. The appearance of human chief cells differs according to the level of their activity (Munger and Roth 1963). Active chief cells are characterized by large Golgi complexes with which are associated numerous vesicles and small membrane-bound granules, the latter probably representing prosecretory granules; larger secretory granules proper are rare, cytoplasmic glycogen sparse, and much of the cytoplasm is taken up by flattened sacs of granular endoplasmic reticulum aggregated into parallel arrays. In contrast, the cytoplasm of inactive chief cells contains only small Golgi complexes with which are associated only a few vesicles and a small number of membrane-bound secretory granules arranged in groups; there is abundant glycogen and many lipofuschin granules but the sacs of granular endoplasmic reticulum are rare and dispersed. In the normal

human parathyroid gland inactive chief cells outnumber the active variety by a ratio of 3–5:1.

The active chief cells synthesize, package and then secrete parathyroid hormone. It is generally assumed that the dense-cored, membrane-bound granules found in the parathyroid chief cells of all mammalian species investigated contain parathyroid hormone, although this remains to be proved (Capen and Roth 1973). There follows a period of gradual involution during which the granules first become peripheral in position and then, under the appropriate stimulus (*vide infra*), their membranes fuse with the plasmalemma, and their contents, presumably including parathyroid hormone, are released. Involution continues with an increase in lysosomal activity and a reduction in size and complexity of the Golgi complexes and the granular endoplasmic reticulum; glycogen reaccumulates, lipofuschin granules form, and the cells enter a temporary 'inactive' phase. In contrast to the thyroid, where the activity of adjacent cells is synchronized, each chief cell of the parathyroid appears to pass through the secretory cycle independently (Roth and Capen 1974).

A second cell type, the *oxyphil* (or *eosinophil*) cell, appears in the parathyroid glands just before puberty and increases in number with age (Roth 1962). Only in man, the macaque monkey and in cattle have such cells been described. The oxyphil cells are larger than the chief cells and contain more cytoplasm, which by light microscopy appears granular and which stains deeply with eosin. The oxyphil nucleus is also smaller and more darkly staining than that of the chief cell. Ultrastructural observations (Munger and Roth 1963; Gaillard *et al.* 1965; Roth and Capen 1974; Capen 1975) have shown that the 'granules' seen by light microscopy are actually mitochondria, which are extremely numerous and tightly packed within the cytoplasm, and which are often bizarre in form. The cytoplasm also contains a few sacs of granular endoplasmic reticulum, some glycogen, and, rarely, small Golgi complexes. No secretory granules have been reported. These findings suggest that the oxyphil cells in normal parathyroid glands are not involved directly in hormone synthesis or secretion, although the copious mitochondria contained in their cytoplasm suggest a high level of metabolic activity. The role of these cells remains to be determined.

The arrangement of the chief and oxyphil cells in the parathyroid gland is shown in **8**.203.

Parathyroid hormone (PTH) is a single-chain polypeptide of 84 amino acid residues (Potts *et al.* 1971), concerned with the control of the level and distribution of calcium and phosphorus in the body (**8**.203). Two other hormones, calcitonin (p. 261) and 1,25-hydroxycholecalciferol, are also involved in the control process. The latter of these is produced by the sequential action of cells of the liver and kidney on vitamin D (O'Riordan 1978). The hormonal control of calcium metabolism has been described in detail by Copp and Talmage (1978). The secretion of PTH is dependent on the concentration of calcium ions in the blood supplying the parathyroid glands. PTH acts directly upon osteocytes and osteoclasts, its rapid initial effect being to increase the rate of release of calcium from bone mineral into the blood, apparently as a result of stimulation of osteocytic osteolysis (Bélanger 1969). It also produces a delayed effect if a high level of secretion is maintained, stimulating internal bone remodelling by promoting osteoclast activity. Changes in the membrane potential of the osteoclasts appears to be involved in the latter effect (Mears 1971). PTH also affects ion transport in the kidney (Puschett 1978), increasing the excretion of phosphate, sodium and potassium, while decreasing that of calcium. It may also affect the intestinal transport of calcium. 1,25-hydroxycholecalciferol, the production of which is regulated by PTH, shares many of these effects and may well be a modulator of PTH action (O'Riordan 1978). The mechanism by which PTH affects its target cells is not yet fully understood; however, adenyl cyclase activation and a consequent rise in intracellular cAMP appear to be involved (Chase and Aurbach 1967; Chabardes *et al.* 1975).

If all the parathyroids are removed, the muscles undergo convulsive spasms (*tetany*) and, as the respiratory muscles (including the laryngeal muscles) are involved, death ensues. These tetanic contractions are due to the fall in blood calcium levels. Excess of parathyroid secretion, such as occurs in tumours of the glands, results in removal of calcium ions from the bones, so that they become soft, a condition known as *generalized osteitis fibrosa*. The calcium ions pass from the bones into the blood (hypercalcaemia) and are excreted in the urine and may cause calcification in the renal tubules with resultant death from kidney disease.

The Chromaffin System

Chromaffin cells or *phaeochromocytes* are classically defined as elements derived from neuro-ectoderm, innervated by pre-ganglionic sympathetic nerve fibres, capable of synthesizing and secreting catecholamines (dopamine, noradrenalin or adrenalin) and storing them in sufficient quantities to give an intense yellow-brown coloration, termed a positive chromaffin reaction, when treated with aqueous solutions of chromium salts, in particular potassium dichromate (Coupland 1965). Groups of such hormone-secreting cells, associated structurally and functionally with the sympathetic nervous system, comprise the *chromaffin system*. This includes (*a*) the medullae of the suprarenal glands, (*b*) the para-aortic bodies, (*c*) the paraganglia proper, (*d*) certain cells of the carotid bodies, and (*e*) small masses of cells scattered irregularly and variably among the ganglia of the paravertebral sympathetic chains, splanchnic nerves and the great (pre-vertebral) autonomic plexuses, and may, therefore, be closely related to various organs (heart, liver, kidney, ureter, prostate, epididymis, ovary, etc.). The distribution of the main components of the chromaffin system in the newborn infant, is shown diagrammatically in Fig. **8**.204.

There are *three main groups* of cells giving a positive chromaffin reaction (Coupland 1976): (1) *true chromaffin cells*, as defined above, (2) *enterochromaffin cells*, found in the epithelial tissue lining the gastrointestinal and respiratory tracts (p. 1364), and (3) *amine-storing mast cells*, found in the connective tissues of the gut, pancreas and liver. The similarity of the ultrastructure of the first two groups, and the ability of all three groups to take up and decarboxylate amino acids (*see* APUD cells, p. 1364), the observation that other non-chromaffin cells in the walls of the gastrointestinal and respiratory tracts, pancreas and other endocrine glands have similar ultrastructural and amino-acid uptake characteristics, and the discovery of paraneurons having many of the features of chromaffin cells in sympathetic ganglia (p. 1124), raise questions about the advisability of continuing to restrict the term 'chromaffin system' to the 'true' chromaffin cells, as it is traditional to do. It may be more appropriate to consider it as part of a diffuse neuro-endocrine system (*vide infra*).

The Diffuse Neuro-endocrine System

The studies of Feyrter (1938) drew attention to the existence of isolated groups of hormone-secreting cells which were not restricted to specific endocrine glands but which were widely scattered throughout the tissues of the body. Feyrter described these cells as *'helle Zellen'*, *clear cells*, and noted that they were particularly prominent in the gut and the pancreas. The clear cells of Feyrter have now been classified as types of 'APUD' cells (Pearse 1966; Pearse 1968; Pearse 1974), cells whose acronymic title is derived from the initial letters of their characteristic amine-handling properties, namely *a*mine *p*recursor *u*ptake and *d*ecarboxylation. Most APUD cells have now been shown to manufacture structurally related peptides which act as *hormones* or as *neurotransmitters*, although in others the main secretion is a similarly acting *amine*. Collectively the APUD cells comprise a 'system' far more extensive than that visualized by Feyrter, including, among others, chromaffin cells (*vide supra*), SIF cells (p. 1124), peptide-producing cells of the hypothalamus (p. 970), pituitary (p. 1440), pineal (p. 1445), parathyroids (*supra*) and placenta, and the Kulchitsky cells of the lung (p. 1259). So far some forty different cell types have been categorized as APUD cells and included in what is now generally described as the *diffuse neuro-endocrine system* (Pearse and Polak 1978). These cells are listed in the accompanying Table.

THE APUD CELLS OF THE DIFFUSE NEURO-ENDOCRINE SYSTEM

I. APUD cells of neural crest origin

Location	*Type*	*Main secretion*	
		Peptide	*Amine*
Thyroid	Parafollicular (C)	Calcitonin	5-HT, Da
Ultimobranchial body	C	Calcitonin	5-HT, Da
Carotid body	Type I Glomus	—	Da, NA
Sympathetic ganglia	SIF	—	NA
Adrenal medulla	Chromaffin	—	Ad
Adrenal medulla	Chromaffin	—	NA
Skin	Melanoblast	—	Promelanin
Urogenital tract	EC	—	5-HT
Urogenital tract	E	—	—

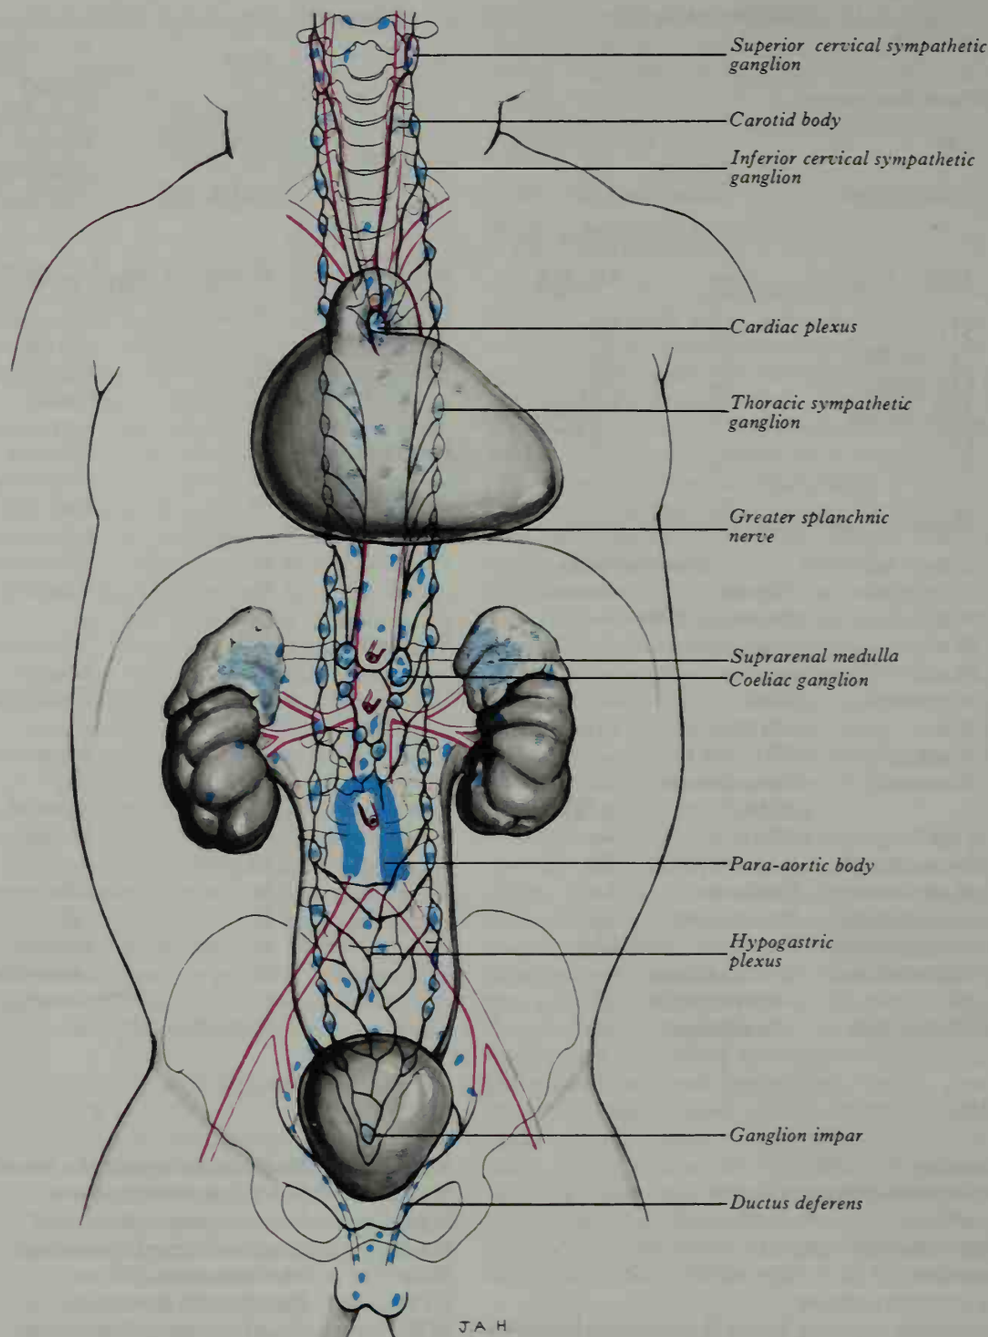
II. APUD cells of placodal or specialized ectodermal origin

Location	*Type*	*Main secretion*	
		Peptide	*Amine*
Hypothalamus	N pv	Oxytocin, CRF	—
	N so	Vasopressin	—
	N sch	—	—
	N dm/vm	TRF	—
	N arc	LHRF	Da
	N ant/post	SRF, CRF	—
	N periv	Somatostatin	—
Pineal gland	P	LHRF	5-HT, MT
Parathyroid	Chief	PTH	—
Pituitary	Somatotroph	Somatotropin	Da
	Mammotroph	Prolactin	Da
	Gonadotroph	Follitropin	Da
	Gonadotroph	Lutropin	Da
	Corticotroph	Corticotropin	—
	M	Melanotropin	T
	Thyrotroph	Thyrotropin	Da

II. (continued)

Location	*Type*	*Main secretion*	
		Peptide	*Amine*
Placenta	Endocrine	Gonadotropin	—
	Endocrine	Somato-mammotropin	—
	Endocrine	Corticotropin	—

III. APUD cells of disputed origin (possibly endodermal)



Location	*Type*	*Main secretion*	
		Peptide	*Amine*
Pancreas	A	Glucagon	5-HT
	B	Insulin	5-HT
	D	Somatostatin	Da
	D_1	VIP-like	Da
	P	Bombesin-like	—
	PP	Pancreatic polypeptide	Da
Stomach	A	Glucagon	—
	D	Somatostatin	—
	ECL	—	H?
	EC_1	Substance P	5-HT
	G	Gastrin, Enkephalin	—
	X	—	—
Intestine	D	Somatostatin	—
	D_1(H)	VIP	—
	EC_1	Substance P	5-HT
	EC_2	Motilin	5-HT
	EC_n	—	5-HT
	I	Cholecystokinin	—
	K	GIP	—
	L	Enteroglucagon	—
	N	Neurotensin	—
	S	Secretin	—
Lung	Kulchitsky (P_a)	—	—

ABBREVIATIONS

Ad	Adrenalin
CRF	Corticotropin releasing factor
Da	Dopamine
GIP	Gastric inhibitory peptide
H	Histamine
5-HT	5-hydroxytryptamine
LHRF	Luteotropin releasing factor (Luteinizing hormone releasing factor)
MT	Melatonin
NA	Noradrenalin
N ant/post	Anterior and posterior nuclear 'zones' of hypothalamus
N arc	Nucleus arcuatus (Nucleus infundibularis)
N dm/vm	Nucleus dorsomedialis/ventromedialis
N periv	Nuclei periventriculares
N pv	Nucleus paraventricularis
N sch	Nucleus suprachiasmaticus
N so	Nucleus supraopticus
PTH	Parathyroid hormone
SIF	Small intensely fluorescent
SRF	Somatotropin releasing factor
T	Tryptamine
TRF	Thyrotropin releasing factor
VIP	Vasoactive intestinal peptide
—	Unidentified

In 1966, Pearse proposed that cells manufacturing peptide hormones shared a common set of cytochemical characteristics, the most striking being related to the production of biogenic amines (adrenalin, noradrenalin, dopamine, 5-hydroxytryptamine, etc.) and suggested that the uptake of 5-hydroxytryptophan (5-HTP) and its decarboxylation to 5-hydroxytryptamine (5-HT) could be linked to the process of peptide hormone production in general. It was from this concept that the designation 'APUD' cell arose (Pearse 1968). Pearse (1977) has also suggested that all cells of the APUD series are derived from *neuroendocrine-programmed cells* of the *ectoblast*, a proposition in need of revision, since the investigations of others suggest that some APUD cells, such as the gastro-entero-pancreatic endocrine cells (p. 1364), may be similarly programmed but of *endodermal* origin (Leblond and Cheng 1976; Le Douarin 1978).

In Pearse's opinion, the APUD cells may collectively be considered as a third division of the nervous system, acting as third-line effectors to support, modulate or amplify the actions of neurons in the autonomic and somatic divisions and of each other. They possess activities which are slower in onset and longer in duration than those of cells in the autonomic division, which in turn bear a similar functional relationship to the faster-acting neurons of the somatic division. The various secretions of the APUD cells (the cells of the diffuse neuro-endocrine system) may act upon *contiguous* cells, upon *groups of nearby* cells, or upon *distant* cells after transport in the blood; they may, in this respect, be considered as intermediate between the locally-acting transmitters produced by neurons and the distantly-acting secretions of the discrete endocrine glands. The diffuse neuroendocrine system thus complements and links the nervous and endocrine systems, *all three systems* interacting to provide a sensitive mechanism allowing for homeostatic control.

8.204 The principal aggregations of 'classical' chromaffin tissue in the human neonatal child. The aggregates in stippled blue lie deep to overlying structures.

It has been suggested that deviations in the relative levels of the secretions of the different cell types of the diffuse neuroendocrine system may result in many of the disorders currently described as psychosomatic (Pearse and Polak 1978) or frankly psychotic (Webster 1978). If this proves to be so, then the growing understanding of this system may lead to significant clinical progress in their treatment.

The Suprarenal Glands

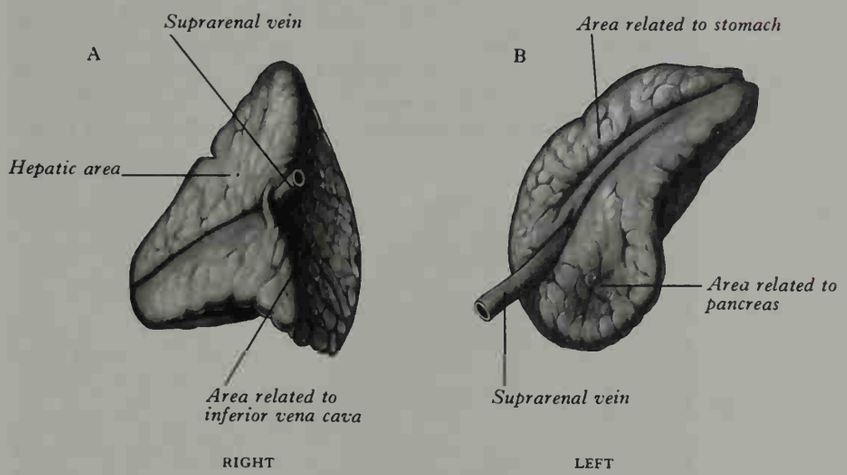
The suprarenal (or adrenal) glands (**8**.98, 205, 206) are two small bodies of a yellowish colour, flattened anteroposteriorly, and situated one on each side of the median plane, behind the peritoneum, and immediately anterosuperior to the superior pole of each kidney. They are surrounded by areolar tissue containing a considerable amount of perinephric fat (p. 1389). They are enclosed, together with the kidneys, in the renal fascia, but are separated from the kidneys by a little fibro-areolar tissue. Each gland consists of an external cortical zone, which is rich in lipids and contains no chromaffin tissue, and an internal medulla, which stains deeply with chromic salts. In man it is not uncommon to find small masses of tissue, identical with the suprarenal cortex, in the neighbourhood of the gland or in other situations. They are termed '*cortical bodies*'. Ontogenetically, phylogenetically, structurally, and functionally, the cortex and the medulla of the suprarenal gland are distinct from each other, but together they constitute a single topographical entity.

The right gland is somewhat pyramidal, resembling an irregular tetrahedron; the left is semilunar, and is usually larger and extends to a more cranial level than the right. Each gland in the adult measures about 50 mm vertically, 30 mm transversely, and 10 mm in the anteroposterior plane, and weighs about 5 g. (the medulla being about one-tenth of the total weight); but all these measurements are variable. At birth the gland is about one-third of the size of the kidney, whereas in the adult it is only about one-thirtieth. The adult gland is little larger than it is at birth. This change in proportions is not only due to renal growth but also to

the fact that after birth the gland begins to diminish in size, due to the involution of the fetal cortex (*see* p. 175). By the end of the second month its weight is only about one-half of that at birth. In the latter half of the second year the gland begins to increase in size and gradually attains its birth weight at or slightly before puberty, after which it only slightly increases in weight in adult life.

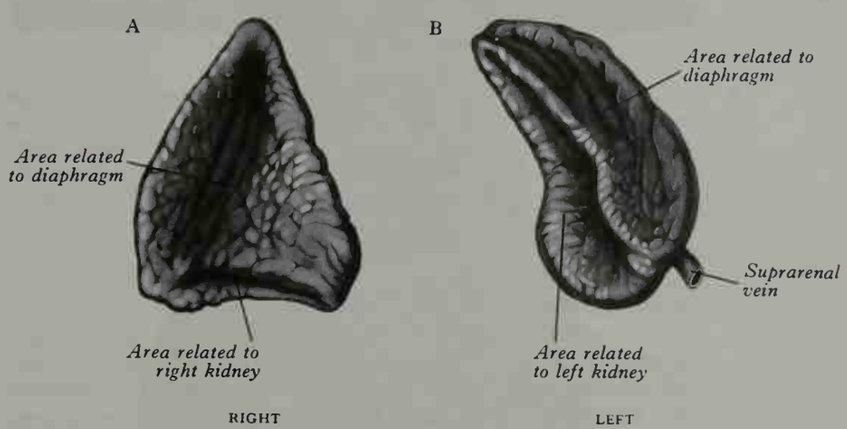
RELATIONS OF THE SUPRARENAL GLAND

The right suprarenal gland (**8**.111) is situated posterior to the inferior vena cava and the right lobe of the liver, and anterior to the diaphragm and superior pole of the right kidney. It is roughly triangular; the base, which is inferior, is in contact with the medial and anterior surfaces of the superior pole of the right kidney. Frequently the base overlaps the upper part of the medial border of the right kidney and not its superior pole. The *anterior surface* faces a little laterally, and presents a medial, narrow, vertical area, not covered by peritoneum, and posterior to the inferior vena cava, and a lateral, somewhat triangular, in contact with the liver. The upper part of the latter surface is devoid of peritoneum, and is in contact with the inferomedial angle of the bare area of the liver, while its inferior part may be covered by peritoneum, reflected on to it from the inferior layer of the coronary ligament; occasionally the duodenum overlaps this area. A little inferior to the apex, and near the anterior border of the gland, there is a short sulcus, forming the hilum, from which the right suprarenal vein emerges to join the inferior vena cava. The *posterior surface* is divided into upper and lower parts by a curved ridge; the superior, slightly convex, rests against the diaphragm; the inferior, concave, is in contact with the superior pole and the adjacent part of the anterior surface of the right kidney. The thin *medial border* of the gland is related to the right coeliac ganglion, which is medial to it inferiorly, and to the right inferior phrenic artery, as the vessel courses superolaterally on the right crus of the diaphragm.



The left suprarenal gland (**8**.111) is crescentic, its concavity being adapted to the medial border of the superior pole of the left kidney. Its medial aspect is convex, its lateral concave; its superior border is sharp, the inferior rounded. Its *anterior surface* has two areas: a superior, covered with the peritoneum of the omental bursa, which separates it from the cardiac end of the stomach and sometimes from the posterior extremity of the spleen; an inferior, which is not covered with peritoneum, but is in direct contact with the pancreas and splenic artery. The hilum, which faces ventrocaudally, is near the lower part of the anterior surface. From it the left suprarenal vein emerges to join the left renal vein. Its *posterior surface* is divided into two areas by a ridge; the lateral adjoins the kidney, the medial and smaller is in contact with the left crus of the diaphragm. The convex *medial border* is related to the left coeliac ganglion, which is inferomedial, and to the left inferior phrenic and left gastric arteries, as they ascend on the left crus of the diaphragm.

Small *accessory suprarenal glands*, which may consist of cortical tissue only, often occur in the areolar tissue around the principal glands; they are sometimes present in the spermatic cord and epididymis, and in the broad ligament of the uterus.



STRUCTURE OF THE SUPRARENAL GLANDS

If a suprarenal gland is cut across (**8**.207), it is seen with the naked eye to consist of an outer part, called the *cortex*, which is yellow in colour and forms the main mass of the gland, and a thin inner part, called the *medulla*, which forms only about one-tenth of the whole gland and is dark red or pearly grey in colour, depending on its content of blood. The medulla is completely enclosed by the cortex, except at the hilum, where the suprarenal vein emerges from the gland. The gland is invested by a thick, collagenous capsule from which trabeculae pass to varying depths into the cortex; the capsule contains a rich plexus of arteries from which branches pass into the gland.

The suprarenal cortex is seen on histological examination (**8**.208, 209) to consist of three zones of cells. The outer is immediately subjacent to the capsule and is called the *zona glomerulosa*; it consists of small polyhedral cells arranged in rounded groups or curved columns, the cells having deeply staining nuclei and a scanty basophilic cytoplasm in which a few lipid droplets may be present. Ultrastructurally (Lever 1955; Long and Jones 1967; Bloodworth and Powers 1968; Shelton and Jones 1971), the cytoplasm contains numerous microtubules, characteristic elongated mitochondria, and abundant agranular endoplasmic reticulum. The latter feature is typical of cells which synthesize steroids elsewhere in the body, and also in the deeper layers of the suprarenal cortex (*vide infra*). The zona glomerulosa is relatively poorly developed in man. Internal to it is the broader *zona fasciculata*; this consists of large polyhedral cells with basophilic cytoplasm, which are arranged in straight columns two cells thick, with fenestrated venous sinusoids coursing parallel with and between the columns. The cells contain numerous lipid

8.205A and B The suprarenal glands. Anterior aspect.

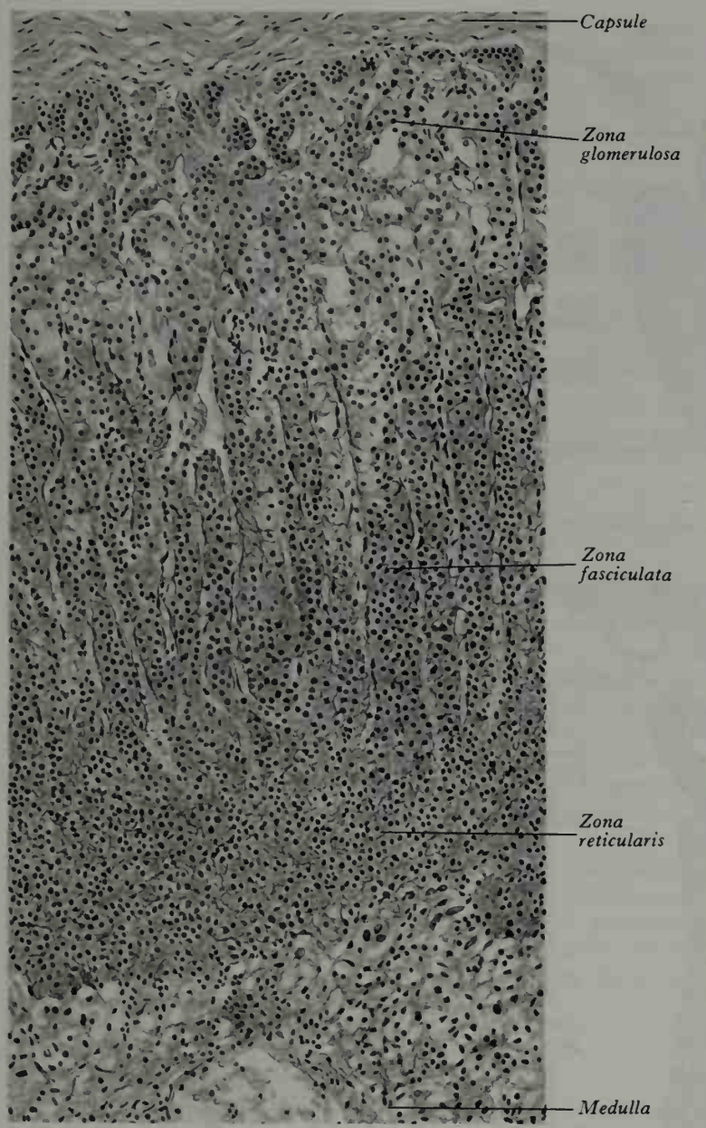
8.206A and B The suprarenal glands. Posterior aspect.

droplets and large amounts of phospholipids, fats, fatty acids and cholesterol, embedded in a complex arrangement of agranular endoplasmic reticulum. The mitochondria are typically spherical with tubular cristae, and the Golgi complex is extensive.

The innermost zone of cortex is called the *zona reticularis*; it consists of branching and anastomosing columns of rounded cells. Their cytoplasm contains much agranular endoplasmic reticulum, numerous lysosomes, and some pigment bodies which may be evidence of degeneration. It is believed by some workers that the cells in the zona glomerulosa, particularly those in its deeper part, undergo continuous proliferation, some of the newly formed cells migrating into the zona fasciculata and thence to the zona reticularis; in the latter the cells degenerate and are absorbed, but conclusive evidence is lacking. Autoradiographic studies indicate that most of the cell proliferation occurs in the zona glomerulosa and outer reticularis, but mitoses are also found in the other regions of the cortex (Reiter and Hoffman 1967). There is certainly little ultrastructural indication of cell death in the zona reticularis.

The deeper part of the zona fasciculata becomes significantly wider in pregnancy (Whiteley and Stoner 1957) and, in the summer, in women of childbearing age (MacKinnon and MacKinnon 1958). It has also been noted that atrophy of the cortex in old age (in males) is greatest in the deeper part of the zona fasciculata and least in its periphery (MacKinnon and MacKinnon 1960). The cells of the cortex produce various hormones and, particularly those of the zonae fasciculata and reticularis, are very rich in *ascorbic acid* (*vitamin C*). The cells of the zona glomerulosa appear to produce *aldosterone*, which affects electrolyte and water balance in the body tissues; the cells in the zona fasciculata produce hormones that maintain carbohydrate balance, in particular *cortisol* (*hydrocortisone*); the cells of the zona reticularis may produce sex hormones (*progesterone*, *oestrogens* and *androgens*). The cortex is essential to life; complete removal is lethal unless replacement therapy is instituted. The cortex appears to exercise a control over lymphocytes and lymphoid tissue, and an increase in secretion of corticosteroids is associated with a reduction in the number of lymphocytes. In some mammals the cortex undergoes cycles of hypertrophy and regression during the oestrous cycle. Between the cells of the cortex are sinusoids, into which most of the capsular vascular plexus and cortical arteries open. Some arteries pass straight through the cortex to supply medullary sinusoids. The cortical sinusoids finally discharge blood into the medullary sinusoids. The endothelial cells of the sinusoids are phagocytic and belong to the macrophage (reticulo-endothelial) system (p. 765).

1458 8.207 Vertical section through a whole adult human suprarenal gland.



The development of the suprarenal gland is described on p. 175. At birth, the relatively large size of the suprarenal is due to the very thick *fetal cortex* (Johannisson 1968), the *definitive cortex* forming only a thin peripheral zone. About the time of birth the fetal cortex begins to undergo regression and it has largely disappeared after a few weeks. Too rapid involution of this cortex may be complicated by fatal haemorrhage in the suprarenal glands. This transient fetal cortex occurs only in anthropoids. There is no conclusive evidence that it produces androgenic hormones. It is very poorly developed in anencephalic fetuses. It does not represent the X-zone (or androgenic zone) occurring, for instance, in the young mouse as a zone surrounding the medulla (Jones 1957).

The suprarenal medulla is composed of groups and columns of *chromaffin cells* (or *phaeochromocytes*) with wide venous sinusoids permeating between them. Small groups of nerve cells, or even single nerve cells, occur here and there in the medulla.

The chromaffin cells synthesize and secrete noradrenalin and adrenalin into the venous sinusoids, the release being under preganglionic sympathetic control (*see* Coupland 1965*a*, for review). In several species of mammals these substances have been identified in two distinct cell types (Yates *et al.* 1962), the noradrenalin storing cells usually being situated more peripherally than those which store adrenalin. All the cells, however, are large columnar elements which are arranged in rows one cell thick, along the margins of the venous sinusoids. The bases of the cells, near which their nuclei are situated, point away from the sinusoids, and adjoin expanded extracellular spaces, into which nerve terminals penetrate to synapse with the chromaffin cells. The latter may form follicular groups, although these are not of the same type of organization as the thyroid follicles (Al-Lami 1970). The cytoplasm of the chromaffin cells is basophilic, and ultrastructurally shows a well-developed granular endoplasmic reticulum, mitochondria and Golgi complex, indicating a high metabolic activity (Al-Lami 1970; Coupland 1965*b*). Numerous secretory vesicles are also present. In noradrenalin-storing cells, these are typically rounded or ellipsoidal bodies which, after treatment with aldehyde and osmium, are highly electron-dense. In adrenalin-storing cells, after similar treatment, the vesicles have a paler appearance (Coupland *et al.* 1964), often with a clear zone between the granular contents and the bounding membrane. In the human suprarenal, cells with mixed adrenalin and noradrenalin vesicles have been reported (Brown *et al.* 1970) so that both may be secreted from the same cell. The vesicles are released at the cell apices into the perivascular space, and gain access to the circulation through the thin endothelial lining of the venous sinusoid, which is fenestrated (Elfvin 1965; Al-Lami 1969).

The sinusoids open into the suprarenal vein at the hilum of the gland. Normally, little adrenalin and noradrenalin are secreted, but under such conditions as fear, anger and stress, the secretion is considerably increased. Noradrenalin produces cardiac acceleration, vaso-constriction, raised blood pressure, etc., whilst adrenalin has a more marked effect on carbohydrate metabolism. Unlike the cortex, the medulla of the suprarenal is not essential to life, and its removal has no apparent effect. The chromaffin cells of the medulla develop and migrate from the neural crests (sympatho-chromaffin tissue, p. 175). The chromaffin reaction (brown staining of the granules in the cells by potassium bichromate due to oxidation of the adrenalin and noradrenalin in the granules) is positive in the fifth month of fetal life, but adrenalin is present as early as the third month (Keene and Hewer 1927).

Interaction between cortex and medulla. It is only in mammals that the chromaffin tissue of the suprarenal becomes almost completely enclosed by cortical tissue. In elasmobranches (e.g. the dogfish) the cortical tissue exists as a pair of structures between the kidneys, the *inter-renal bodies*, whereas the chromaffin tissue is completely separate and forms segmentally

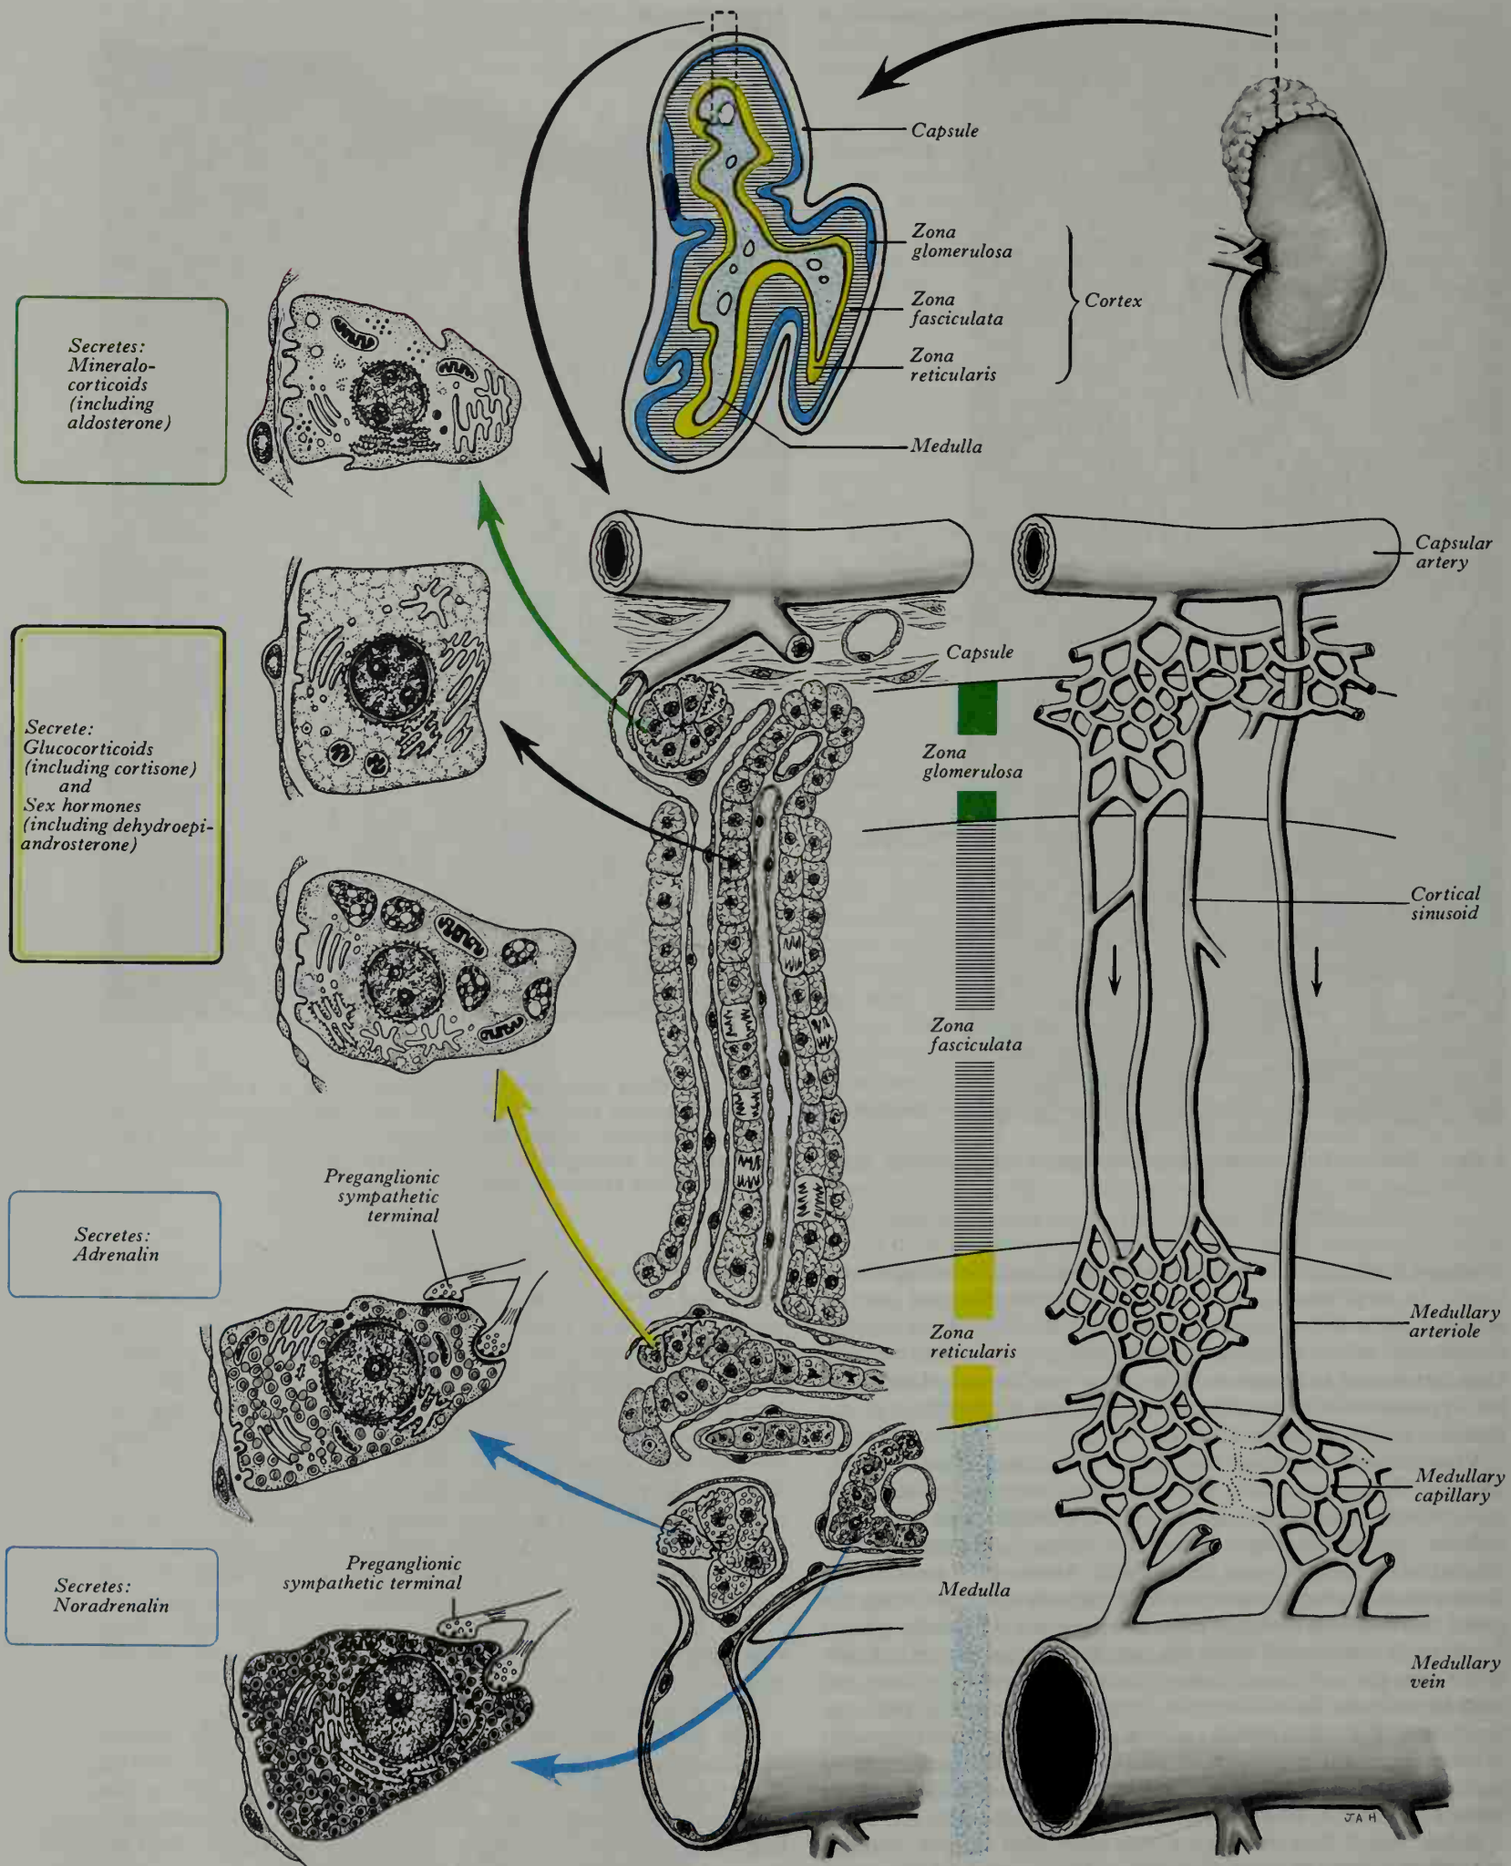
arranged bodies closely related to the ganglia of the sympathetic trunk. In amphibia and birds, cords of chromaffin and cortical cells are intimately associated, but a true medulla is not formed Coupland (1965*a*). It appears that the presence of cortical tissue in close proximity to the chromaffin tissue may be associated with the appearance of adrenalin, formed by the methylation of the primary amine, noradrenalin (*vide infra*).

Vessels and nerves. The suprarenal gland is exceedingly vascular. It is supplied by three groups of vessels, the superior, middle and inferior suprarenal *arteries*, which arise from the inferior phrenic artery, abdominal aorta, and renal artery respectively (Harrison and Hoey 1960). Most of the branches of the suprarenal arteries ramify over the capsule before entering the gland and dividing within it to form a narrow subcapsular plexus from which fenestrated sinusoids pass around the clusters of cells in the zona glomerulosa and then inwards between the columns of cells in the zona fasciculata to a deep plexus located in the zona reticularis. From this, small venules pass between the chromaffin cells of the medulla to the medullary veins, which they enter by passing between prominent bundles of longitudinally-arranged muscle fibres. It would appear that these bundles of fibres regulate blood flow through a vascular 'dam' at the cortico-medullary junction, that is, at the deep aspect of the zona reticularis (Dobbie and Symington 1966). Since this would in turn control the rate of blood flow through the zona reticularis and zona fasciculata, it could provide a mechanism for control, in part, of the availability of ACTH to the secretory cells of these regions, and hence of its possible uptake (Griffiths and Cameron 1975).

Some major arterial branches bypass the system described above and supply the medulla directly. It thus has a dual blood supply, both indirect and direct (**8**.209); blood reaching it by the indirect route, that is, by way of the cortical sinusoids, is probably sufficiently rich in glucocorticoids to induce and maintain the synthesis of phenylethanolamine-N-methyl-transferase, an enzyme needed for the synthesis of adrenalin from noradrenalin, whereas that reaching it by the direct, non-cortical route is not. Whether a medullary chromaffin cell can make adrenalin or noradrenalin depends on the presence or absence of this enzyme, and may well be determined by its blood supply (Wurtman and Pohorecky 1971); changes in the relative blood flow along the two routes could thus have profound physiological consequences.



The medullary veins drain into the *suprarenal vein* which emerges from the hilum of the gland; the right opens into the inferior vena cava, that on the left into the left renal vein.

The *lymph* vessels end in the lateral aortic nodes (p. 795).

The *nerves* are exceedingly numerous. They are mainly myelinated preganglionic sympathetic fibres and are described on p. 1134. They are distributed to the chromaffin cells in the medulla of the gland. The activities of the suprarenal cortex are largely controlled by adrenocorticotropic hormone (ACTH) secreted by the anterior lobe of the hypophysis.

Applied Anatomy. Various clinical conditions may occur as the result of lesions affecting the cortex or medulla of the suprarenal and they are attributable to the effects of excess or deficiency of the secretions of these parts of the gland.

Atrophy or tuberculosis of the suprarenal cortex, with

8.209 The suprarenal gland, displaying its gross sectional appearance, histology, vasculature, and ultrastructure. Brief functional summaries are appended.

consequent insufficiency of cortical secretion, results in Addison s disease, which is characterized by muscular weakness, low blood pressure, anaemia, brownish pigmentation of the skin, changes in electrolyte and fluid balance of the tissues, and terminal circulatory and renal failure. Excessive cortical secretion due to tumours or hyperplasia of the cortex may produce various effects. (1) In the adult, Cushing's syndrome may result, characterized by obesity, excessive hairiness of the face and trunk, diabetes mellitus, and impotence and hypogonadism in the male or amenorrhoea in the female. (2) In women, masculinization of the secondary characters (virilism) may occur due to excessive secretion of androgenic hormones. (3) In men, feminization, particularly breast enlargement, may occur. (4) In children, there may be precocious body growth and development of the external genital organs, with early menstruation in the female. (5) In the female fetus, hyperplasia of the cortex occurring between the third and fourth months gives rise to the condition of female pseudohermaphroditism, the excessive androgen secretion interfering with the differentiation of the urogenital sinus which occurs at this time, so that the urethra and vagina open into a persistent urogenital sinus; the clitoris also enlarges and the external genital organs thus resemble those of the male. In the male fetus, cortical hyperplasia at this time causes excessive development of the external genital organs.

Bilateral removal of the suprarenal glands (adrenalectomy) is practised in the treatment of some advanced, inoperable cases of disseminated carcinoma of the breast or prostate, which do not respond to radiotherapy and where the malignant changes are considered to be dependent on hormonal control (androgens or oestrogens). The suprarenal glands can be demonstrated radiologically if air is injected into the perirenal fat.

Tumours of the suprarenal medulla and of the para-aortic bodies (phaeochromocytomata) may occur; the consequent excessive secretion of adrenalin and noradrenalin produces attacks of palpitations, excessive sweating, pallor of the skin, hypertension, headaches, and, if the tumours are of long duration, retinitis and vascular changes in the kidneys.

THE PARAGANGLIA

The paraganglia (Zuckerkandl 1901; Köhn 1903) are generally defined as extra-adrenal aggregations of chromaffin tissue (p. 1458), widely distributed along and within the autonomic nervous system (Coupland 1965*a*; Mascorro and Yates 1971; Hervonen *et al.* 1978*a*). Cells similar to those which characterize the paraganglia proper (which, as their name implies, adjoin various autonomic ganglia) are also found within sympathetic ganglia, where they are referred to as *small, intensely fluorescent* (SIF) *cells* (Williams *et al.* 1975), in the walls of various viscera and in a variety of retroperitoneal and mediastinal locations (Ramsdale *et al.* 1972; Hervonen *et al.* 1976; Hervonen *et al.* 1978*b*). All share a common neuro-ectodermal origin and an ability to synthesize and store catecholamines; their function, however, differs with their location, the intraneurally disposed acting as interneurons (p. 809) while the remainder are sources of a variety of endocrine secretions, including a tryptophan-containing protein as well as catecholamines (Hervonen *et al.* 1978*a*). This diffuse collection of extra-adrenal chromaffin tissue has been referred to as the *paraganglion system* (Mascorro and Yates 1975); it is particularly prominent in the fetus, where it provides the main source of catecholamines while the adrenal medulla is in process of development (West *et al.* 1955; Kovrishko 1964). Although many paraganglia degenerate soon after birth (Coupland 1965*a*), the application of specific fluorescent histochemical techniques for the detection of catecholamines (Eränkö 1967) has led to the location of large numbers of persistent, though often minute, paraganglia in adult man and other mammals, and to the need for a revision of the earlier concept of general involution of the paraganglia after birth.

Paraganglia contain two characteristic varieties of cell: *type I* (or granule-containing) and *type II* (or satellite) cells (Mascorro and Yates 1975). The type I cells each have a large nucleus, round or elongated mitochondria, some granular endoplasmic reticulum also well-developed Golgi complexes, glycogen deposits, and numerous, membrane-bound, electron-dense cytoplasmic granules containing catecholamines and, possibly, the tryptophan-containing protein mentioned earlier; these features, together with their neuro-ectodermal origin, place them in the APUD cell category (Pearse 1969; Pearse and Polak 1974). On the basis of their cytoplasmic density, the type I cells can be classified as either 'light' or 'dark'; although the general belief is that 'dark' cells appear so as a fixation artefact (Mugnaini 1965; Benedeczky and Smith 1972), an alternative possibility is that they and the 'light' cells represent different stages of a secretory cycle. The type II cells lack cytoplasmic granules, and have processes which envelop adjacent type I cells either partially or completely.

The type I cells of the paraganglia receive a 'preganglionic' sympathetic innervation (Mascorro and Yates 1974) like that of the chromaffin cells of the adrenal medulla (Cummings 1969). For much of their length the non-myelinated nerve fibres are separated from the type I cells by Schwann cell cytoplasm and the cytoplasmic projections of the type II cells, approaching them closely only at synapses. The presynaptic endings contain mitochondria, glycogen granules and many synaptic vesicles, most of which are electron-lucent, although some have electron-dense cores. There is evidence that in vagal paraganglia such endings are cholinergic and efferent in type (Chen and Yates 1970).

The paraganglia are well vascularized, and the secretory type I cells generally lie next to one or more fenestrated capillaries, often with only basal lamina intervening between them, although fine collagen fibres and the cytoplasmic processes of type II cells may also be present. There is thus little to obstruct the passage of hormones from the type I cells to the blood system (Mascorro and Yates 1975).

Currently available evidence suggests that the paraganglia should be considered as endocrine organs whose secretory cells manufacture catecholamines and proteins, storing them as cytoplasmic granules until stimulated to release them by intrinsic or extrinsic factors. As well as having a remote endocrine effect, a local paracrine action of these secretions on nearby cells cannot be ruled out. The paraganglia collectively comprise a diffuse system which may act throughout life as a source of catecholamines additional to those provided by the adrenal medulla, and as such assume a role of considerable metabolic and clinical significance (*vide infra*).

THE PARA-AORTIC BODIES

The para-aortic bodies progressively develop during fetal life and attain their maximum size in the first three years of post-natal life, when the largest take the form of two elongated, brownish bodies, about 1 cm long, which lie one on each side of the abdominal aorta in the region of origin of the inferior mesenteric artery. They are usually united across the front of the aorta by a horizontal mass, which lies immediately above the origin of the inferior mesenteric artery, so as to form collectively an inverted horseshoe, or H-shaped arrangement. They are intimately related to the intermesenteric and superior hypogastric plexuses. The constituent cells undergo dispersal and some atrophy, and by the age of fourteen years have been said to be completely disintegrated (*see* Coupland 1965*a*). When well-developed, they consist of masses of polygonal chromaffin cells embedded in a wide-meshed capillary plexus. The chromaffin cells of the para-aortic bodies secrete noradrenalin.

Other small chromaffin bodies are found in the fetus in all parts of the abdominal and pelvic prevertebral sympathetic plexuses. They reach their maximum size between the fifth and eighth months of fetal life, and in the adult they are present as discernible structures mainly in the vicinity of the coeliac and superior mesenteric arteries, whilst only microscopic collections of chromaffin cells persist in association with the lower parts of the intermesenteric plexus.

Although the chromaffin cells of the sympathetic ganglia, as noted above, may act as interneurons, those of the other extra-adrenal chromaffin tissues described above are endocrine in nature and probably subserve the adrenal medulla as sources of catecholamines (Chen *et al.* 1976), particularly in pre- and early post-natal life when the adrenal medulla and the autonomic

nervous system are not fully differentiated (West *et al.* 1953). Support for this proposition has come from the findings of Coupland and Weakley (1970) that the extra-adrenal chromaffin cells are structurally similar to those of the adrenal medulla. There is also ultrastructural evidence in the rat that the chromaffin cells associated with the nodes of the solar plexus have

8.210A A section of the carotid body, showing nerve fibres distributed to the cells. (de Castro.) *a*, Myelinated fibre dividing into two fine branches; *b*, cell closely surrounded by nerve fibrils; *c*, section of a small nerve, composed of several myelinated fibres; *f*, a nerve fibril apparently ending within the cytoplasm of a cell; *g*, a nerve fibril ending between the cells.

processes extending beyond the ensheathing glial cells towards blood capillaries into which their catecholamines pass (Levkova and Kakabadze 1977).

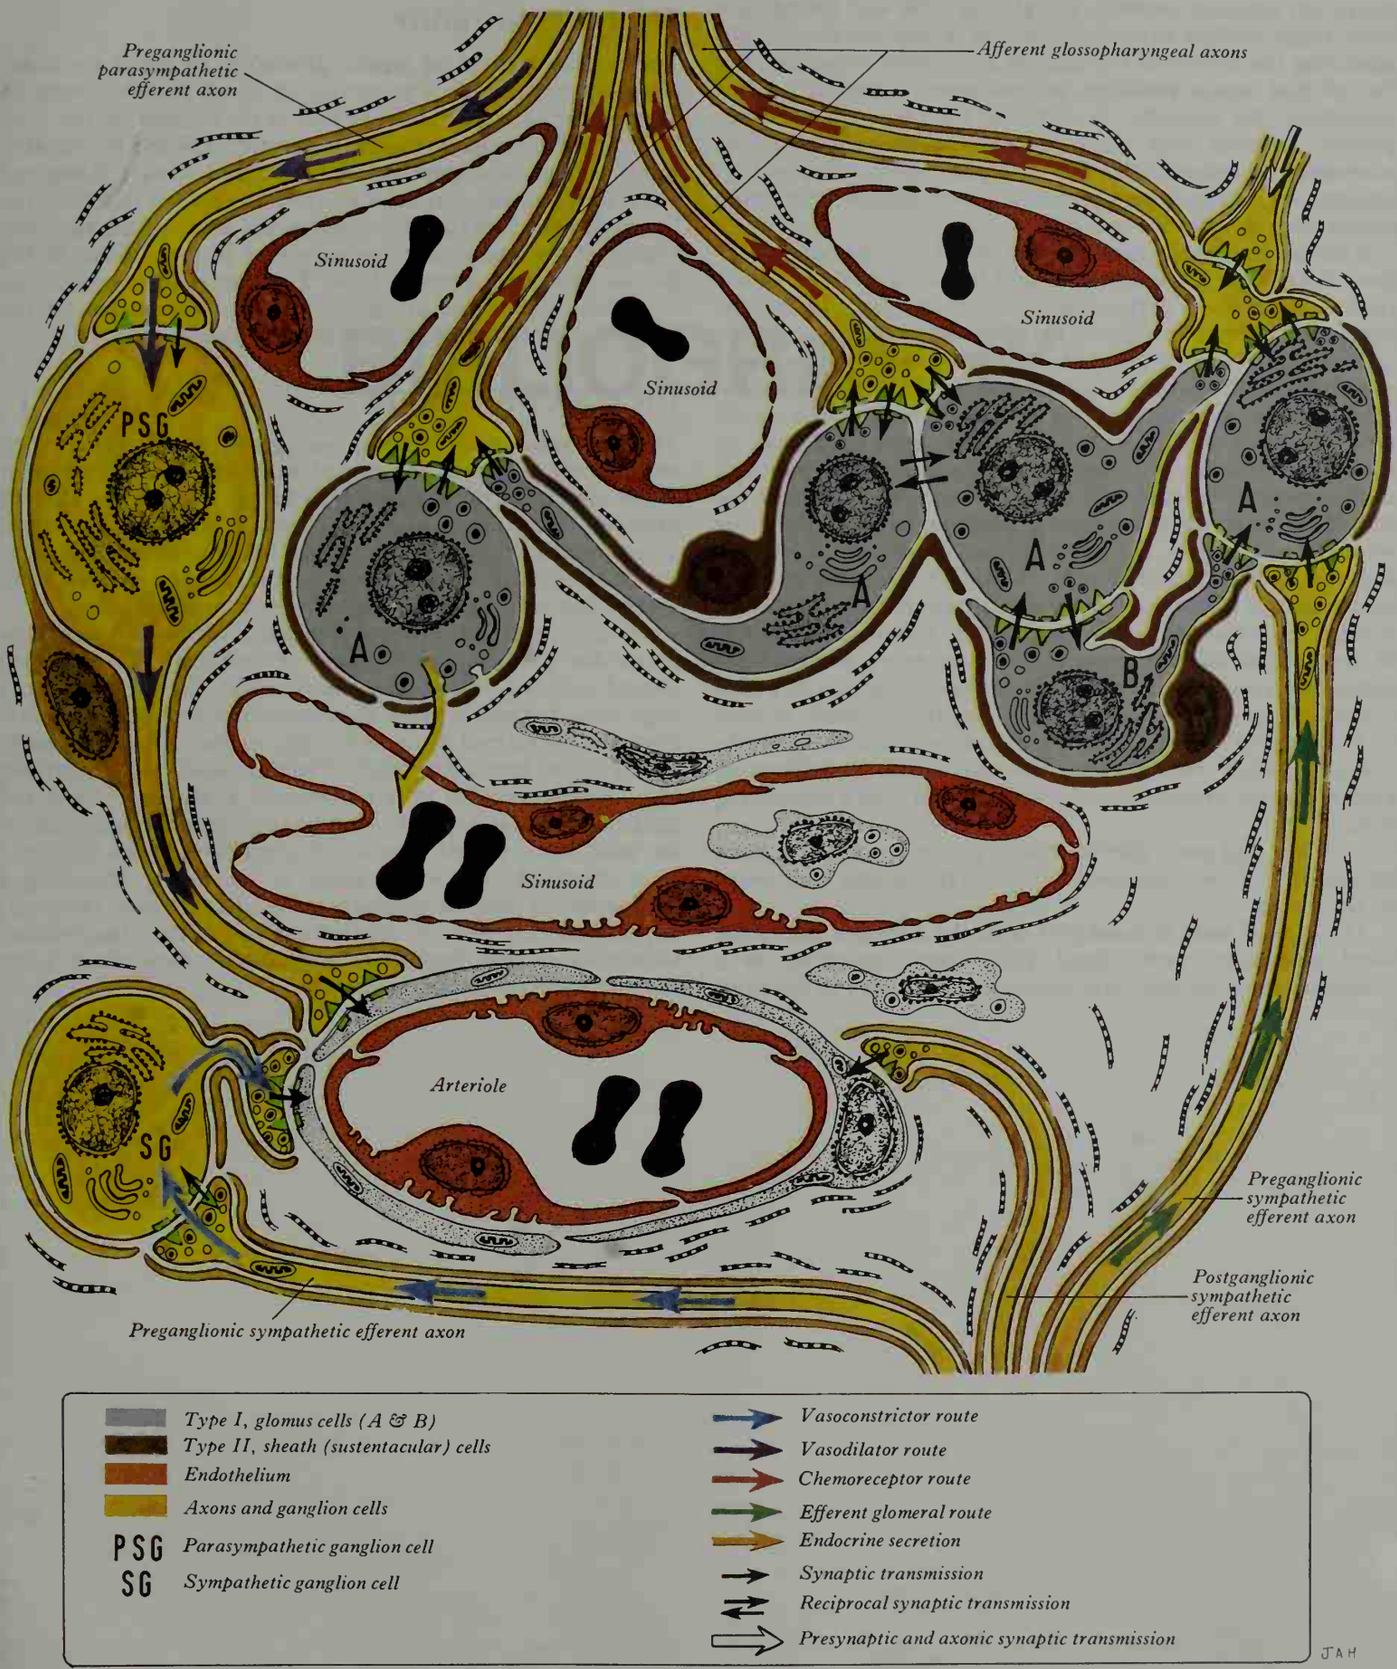
The Carotid Bodies (Glomera Carotica)

The two carotid bodies are reddish-brown, ellipsoidal structures, situated one on each side of the neck, in close relation to the carotid sinus (p. 676). Each is about 5 to 7 mm in height and 2·5 to 4 mm in width and varies slightly in position, being either posterior to the bifurcation of the common carotid artery, or completely or partially wedged in between the commencements of the internal and external carotid arteries, and is attached to, and sometimes partially embedded in, the outer fibrous layer of these arteries. Occasionally the organ is in the form of a number of separate nodules. Aberrant spheroidal 'miniglomera', microstructurally similar to the carotid bodies but with a diameter of 600 μm or less, have been identified in the adventitia and in the adipose tissue of the carotid sinus region in some human cadavers (Garfia 1980). The carotid body is innervated by the carotid branch or branches of the glossopharyngeal nerve, including the *carotid sinus nerve*, and by a fine *plexus* containing glossopharyngeal, vagal and sympathetic components (*see* pp. 1075, 1128 for variations in origin and arrangement). Its copious blood supply is derived from neighbouring branches of the external carotid artery.

Structure and Function

The carotid body is an *arterial chemoreceptor*. When stimulated by hypoxia, hypercapnia or elevated hydrogen ion concentration in the blood, it elicits a reflex increase in the rate and volume of ventilation through neural connexions with the array of respiratory centres in the brainstem. Although its main physiological role is known, it is uncertain which of its diverse components function as chemoreceptors (Chen *et al.* 1976). The carotid body may also be an *endocrine gland*; its *glomus cells* (*vide infra*) are included in the APUD series (p. 1454), which has been extended to include virtually all the specialized cells responsible for peptide hormone production (Pearse 1976), but as yet no specific peptide hormone has been assigned to them. A suggested role in the control of erythropoiesis (Tramezzani *et al.* 1971) has now been refuted (Paulo *et al.* 1973).

The carotid body has a fibrous capsule, whose invading septa divide it into lobules, each containing tightly packed collections of epithelioid '*glomus*' (type I) cells, enveloped by *sheath* (*sustentacular or type II*) *cells* (**8**.210B), the latter separating the former from an extensive anastomosing network of fenestrated sinusoids. Between the sheath cells and the sinusoid endothelium are non-myelinated nerve fibres, Schwann cells, the attenuated processes of connective tissue cells, and collagen fibres (Chen *et al.* 1976). Many of the nerve fibres are afferent, passing between the sheath cells and making synaptic contacts with the glomus cells. Preganglionic efferent fibres pass to the sparse population of parasympathetic and sympathetic *ganglion cells*; these fibres are derived from the carotid sinus and sympathetic nerves (McDonald and Mitchell 1975), while the cells are located either separately or in small groups near the surface of the carotid body. Axons proceed from the ganglion cells to the local blood vessels, the parasympathetic efferent fibres probably causing vasodilation (Biscoe *et al.* 1969) and the sympathetic vasoconstriction (Purves 1970).



'*Glomus*' (glomeral) *cells* are more numerous than sheath cells. They are moderately large, with abundant cytoplasm, and carry a few dendritic processes which extend into neighbouring intercellular spaces. Membrane bound electron-dense granules occur near the Golgi apparatus and close to the plasma membrane. Occasional sites of fusion of the limiting membranes of these granules and the plasma membrane have been found (Hansen 1977). The glomus cells store dopamine (Kobayashi 1969), other neurotransmitters and the protein 'glomin' (Pearse 1969), presumably in these granules; they are now accepted as a variety of chromaffin cell (Böck and Gorgas 1976), although a positive chromaffin response can only be detected by electron microscopy (p. 1458). They have also recently been classified as paraneurons (Fujita 1976). Their granular endoplasmic reticulum is not abundant, but an arrangement similar to neuronal Nissl substance has been described in the human carotid body (Böck *et al.* 1970). In the rat two types of glomus cell are recognized: types A and B (MacDonald and Mitchell 1975). Type A cells have larger and more numerous electron-dense granules than type B cells, and while the former usually have a smooth, globular contour with relatively few stubby dendritic processes, the latter are more irregular and bear several long thin processes.

Nerve endings are seldom found in synaptic contact with type B glomus cells, but at least two types of fibres synapse with type A: of these, over 95 per cent are *chemo-afferent axons* which leave the carotid body in the carotid sinus nerve, having their cell bodies in the sensory ganglia of the glossopharyngeal nerve, while less than 5 per cent are *preganglionic efferent axons* from the cervical sympathetic trunk, which enter the carotid body in company with postganglionic axons from the superior sympathetic ganglion. Apparently no efferent axons from the glossopharyngeal nerve synapse with glomus cells, although some are preganglionic to parasympathetic ganglion cells. In the rabbit, efferent fibres of uncertain origin, presumed to be inhibitory, make synaptic contact with the chemo-afferent axons (Verna 1975). Of the 'afferent' nerve endings, some are presynaptic to type A glomus cells, others postsynaptic, and yet others form *reciprocal synapses* with them. Reciprocal synapses have also been found linking adjacent glomus cells (McDonald and Mitchell 1975); they are dendrodendritic in form (Reese and Shepherd 1972). Similar organizations have been found in several parts of the central nervous system (pp. 829, 831) but not hitherto in the *peripheral* nervous system. The various neural circuits claimed to exist in the carotid body of the rat and rabbit (McDonald and Mitchell 1975; Verna 1975) are shown diagrammatically in Fig. **8**.210. Evidence concerning the human carotid body is awaited with much interest.

Ultrastructural and neurophysiological evidence suggests that the glomus cells could have at least three functions. Firstly, they are known to release neurotransmitters in response to hypoxia

(Eyzaguire *et al.* 1972), and may therefore be *sensory cells*. Secondly, they have an ultrastructure which has led to their being classified as APUD cells (Pearse 1969), and may therefore act as *effector cells* modifying, by varying the release of dopamine from their secretory vesicles, the sensitivity of neighbouring chemoreceptive nerve endings (Biscoe *et al.* 1970). Thirdly, since they have a synaptic input and output, are enveloped by gliaform sheath cells, and have dendritic processes but no axons, they may operate as *interneurons* (McDonald and Mitchell 1975). The simultaneous involvement in multiple functional roles as those postulated above is reminiscent of the possible phylogenetic progenitor neuronal cell.

As stated above, there is no uniform view as to which of the components of the carotid body act as chemoreceptors: *glomus*

8.210B The cellular, neural and vascular architecture of the carotid body. Functional pathways are indicated. (Consult text for detailed discussion.)

cells (Lever *et al.* 1959; Eyzaguire *et al.* 1972), *afferent nerve terminals* (McDonald and Mitchell 1975), and *sheath cells* (Mills and Jöbsis 1972) have all been suggested as possibilities. A recent hypothesis is that the afferent axons and glomus cells co-operate as chemoreceptive units (McDonald and Mitchell 1975). It is proposed that: (1) the afferent nerve endings, interconnected with glomus cells by reciprocal synapses, are the true chemoreceptors; (2) the glomus cells are dopaminergic interneurons which modify the sensitivity of the chemoreceptive endings; (3) the reciprocal synapses between the glomus cells and the afferent axons might mediate an inhibitory feedback loop, the glomus cells inhibiting the activity of the afferent axons with dopamine, and the afferent axons releasing an excitatory transmitter when stimulated, for example, by hypoxia; (4) preganglionic sympathetic neurons may decrease chemoreceptive activity by stimulating dopamine release from some glomus cells; and (5) synaptic interconnexions between adjacent glomus cells could enable them to influence each other.

A further hypothesis implicates the *sheath cells* in chemoreception. It has been proposed (Mills and Jöbsis 1972) that hypoxia could cause changes in the sheath cells which might initiate the firing of adjacent 'free' afferent nerve endings, whilst the glomus cells, with their efferent sympathetic innervation, could form part of a feedback circuit modifying the activity of the afferent axons. About half the cytochrome a_3 of the carotid body is of a special type with a low affinity for oxygen. It has been concluded, by elimination, that this special type of cytochrome a_3 may be located in sheath cell mitochondria. If this is so, then it would make the sheath cells particularly sensitive to hypoxia, for the cytochrome would remain in its reduced state in conditions of oxygen shortage, and this would depress the oxidative metabolism of the sheath cells. It is proposed that this might cause them to release a substance, such as potassium, which would stimulate the activity of the adjacent afferent axons. Since these axons contain large numbers of mitochondria containing a cytochrome a_3 with a high oxygen affinity, they would be able to function normally even in an environment low in oxygen. It is also of considerable interest to speculate what role a local haemodynamic vasodilatator/vasoconstrictor control system would serve in such a monitoring system.

It is clear that many further studies are necessary if the exact mechanisms of chemoreceptor reflexes in the carotid body are to be elucidated.

The carotid body is developed from the mesenchyme of the third pharyngeal arch (Boyd 1937), first appearing as a condensation of the mesenchyme around the artery of the third pharyngeal arch, and its nerve supply is mainly from the nerve of that arch, the glossopharyngeal.

Other small bodies, with a structure similar to that of the carotid bodies, are found near the arteries of the fourth and sixth pharyngeal arches; they hence are close to the arch of the aorta, the ductus arteriosus and the right subclavian arteries, and are supplied by branches of the vagus nerves. They are also believed to function as chemoreceptors.

THE TYMPANIC BODY

The tympanic body (or *jugular glomus*) is an ovoid structure, about 0·5 mm long and 0·25 mm broad, which is in the adventitia of the upper part of the superior bulb of the internal jugular vein. Its structure is similar to that of the carotid body, and presumably it has similar functional associations (Guild 1941; Kjaegaard 1944, 1973). It may consist of two or more masses related to the tympanic branch of the glossopharyngeal nerve or the auricular branch of the vagus, as these nerves lie in their canals in the petrous part of the temporal bone. Tumours of these bodies may occur and may cause symptoms due to involvement of the neighbouring cranial nerves and the middle ear.

THE COCCYGEAL BODY

The coccygeal body (*glomus coccygeum*) is anterior to, or immediately inferior to, the apex of the coccyx, at the termination of the median sacral vessels, which supply afferent and efferent branches to the organ, and it is closely related to the ganglion impar of the sympathetic trunks. It is about 2·5 mm in diameter and is irregularly oval in shape; several smaller nodules with similar structure are found around or near the main mass.

The coccygeal body consists of irregular masses of spherical or polyhedral 'epithelioid' cells, those of each mass being grouped around a dilated, sinusoidal capillary vessel. Each cell contains a large, round or oval nucleus, the cytoplasm surrounding which is clear and not stained by chromic salts, so that it does not clearly belong to the chromaffin system. The sinusoidal vessels form part of a complex system of arteriovenous anastomoses, and the epithelioid cells appear to be modified nonstriated muscle cells of the walls of the vessels. Similar structural formations have long been identified in a wide variety of mammals, occupying a corresponding position, ventral to the caudal vertebrae. However, as yet there have been no detailed analyses of their innervation, ultrastructure and functional associations; these must await anatomical researches of the future.
